We changed the flight length $l_{f\,1}$ of the butterfly B_1 from 5.0 to 0.0 in -0.2 steps, and also changed $l_{f\,2}$ of the butterfly B_2 from 5.0 to 10.0 in +0.2 steps, respectively, where $l_{f\,1} + l_{f\,2} = 10.0$.

Experiment 3: Varying the fraction f_t for the threshold of the scent intensity for two butterflies.

We changed the fraction $f_{t\,1}$ of the butterfly B_1 from 0.60 to 0.20 in -0.01 steps, and also changed $f_{t\,2}$ of the butterfly B_2 from 0.60 to 1.00 in +0.01 steps, respectively, where $f_{t\,1} + f_{t\,2} = 1.20$.

We used the default parameters shown in **Table 1** except the target parameters in each experiment.

4.2 Result of learning factor experiment

The experimental result is shown in **Fig. 2**. A solid line shows the average of each trial result by the two quantum-entangled butterflies. A dashed line shows the average of

Table 1. Default parameters used

The learning factor	1.00
The length of a short straight flight	5.0
The fraction for the threshold of the scent intensity	0.60
The direction chosen	16 directions evenly spread over 2π.
The initial distance of two butterflies	1600.0
The distance which can find the another (termination condition)	20.0
The number of trials	1000

each trial result by the two independent butterflies. These are the same also at latter experimental results, which are **Fig. 2** and **Fig. 3**. The graph shows that the equality of the learning factor reduces the number of total flights to encountering of the two butterflies. Especially, this tendency is remarkable on the quantum-entangled butterflies. It is because the probability distributions of directions which change similarly with equal learning factor let the selection frequency of a direction related to cooperative behavior as shown in Eq.4 and Eq.5 increase.

4.3 Result of length of short straight flight experiment

The experimental result is shown in **Fig. 3**. The number of total flights decreases with increase of the difference of the flight length between two butterflies ($l_{f\,2}$ - $l_{f\,1}$). Especially, this tendency is remarkable on the independent butterflies. It is because the difference of ability decreases the opportunity for disturbing each action of uncooperative butterflies. A large value of $l_{f\,2}$ - $l_{f\,1}$ extinguishes mostly the difference from the quantum-entangled butterflies. When one of the two quantum-entangled butterflies is provided the extremely small flight length, success or failure of their approach depends heavily on a behavior of another butterfly. Hence, probably cooperative behavior is no use.

4.4 Result of fraction for threshold of scent intensity experiment

The experimental result is shown in **Fig. 4**. In the case of independent butterflies, the number of total flights decreases with increase of the difference of the fraction for threshold of scent intensity ($f_{t\,2}$ - $f_{t\,1}$) to $f_{t\,1}$= 0.27 and $f_{t\,2}$ = 0.93. On the other hand in the case of the quantum-entangled butterflies, this tendency is not strong; the number of total flights is the minimum at the fractions: $f_{t\,1}$= 0.35 and $f_{t\,2}$ = 0.85. Even if the quantum-entangled butterflies make a cooperative decision whether to fly or to rest, only one butterfly may judge that it is necessary to fly back when the difference of the fractions is quite large. Thereby, the meaning of cooperative behavior by quantum entanglement diminishes.

5 CONCLUSION

In the model of the quantum-entangled butterflies finding each other, we have simulated the model while changing each the three parameter conditions in order to clarify the influence on the performance to find another butterfly. From the each experimental result, we have proven that the conditions to improve the finding performance are the more equivalent learning factor, the

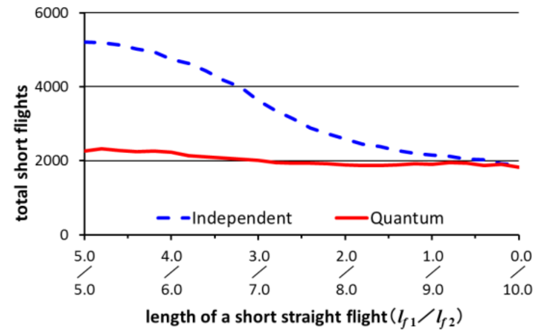

Fig. 3. Total number of short flights needed by the two butterflies to find each other vs. the length of a short straight flight $l_{f\,1}$ and $l_{f\,2}$.

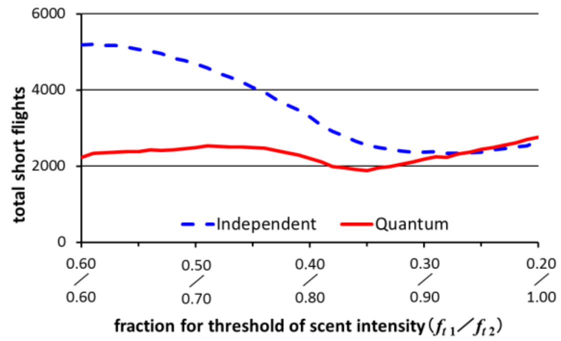

Fig. 4. Total number of short flights needed by the two butterflies to find each other vs. the fraction for threshold of scent intensity $f_{t\,1}$ and $f_{t\,2}$.

bigger difference of the length of a short straight flight, and the bigger difference of the fraction for the threshold of the scent intensity. However, when the difference of each parameter is too large, action of one butterfly is wasted and it may disturb cooperative behavior inspired by quantum entanglement.

Abstract: Our aim is to create a more intelligent form of control for robots that can act autonomously for problem solving in the dynamic environments. The ability to select and modify the action decision policies to achieve the given goals in the most appropriate way as possible, and the easiest and most efficient way of implementation of such policy controls is required. We propose a flexible method for selecting policies of action decision in this paper, using a dynamic planner as the mechanism for determining the policies for action decision making. We proved through experimentation that when a robot cannot achieve its goal using a specific policy, it can modify the given policy to achieve that goal with the use of our method. In particular, for robots in the real world, the error of beliefs due to a false recognition of the sensors may be the reason why a robot cannot achieve its goal, although this situation will not come to light in any simulation. Our method is effective for such situations.

Keywords: Autonomous agent, Intelligent robot, BDI, Real world oriented, Planner

1 INTRODUCTION

With the recent development of advanced robotics, there is a growing expectation for the construction of intelligent robots that can act autonomously by generating plans for achieving their goals in the real world. In particular, such a robot would require the ability to cope with various changes in their environments; for example, when it cannot achieve its goal by using the current plan because of an unexpected change in the real world situation, it must create a new policy of action for achieving its goal.

Our aim is to create such robots using autonomous agents called BDI agents. Since it is now possible to inexpensively and easily obtain small robots, we are currently attempting to equip them with BDI agents and assist them to be able to resolve problems in the real world.

As described in Sec.2, a BDI agent has a native mechanism called "deliberation", which selects a plan to execute immediately from among multiple (currently active) plans for achieving the agent's goals. This mechanism works like the task switching mechanisms of operating systems, and assists the agent in switching goals and gives them a means for easily achieving them. Furthermore, agent designers can separate the codes for switching plans from the codes of the plans themselves. These are part of why the BDI agent is suitable for creating robots that can autonomously solve problems.

However, it would be inadequate to write a deliberation algorithm using the hand-coding manner to achieve a highly flexible switching of plans. A higher-level means to provide a deliberation algorithm is required to infer an appropriate plan depending on the given circumstances of the agents.

In this paper, we propose enhancing the deliberation by introducing a dynamic planner. Human beings normally hold some sort of policy as a higher-level principle for selecting plans for achieving his/her goals, and modify it as necessary to change his/her behavior. Our proposal is to implement this method on an agent using a dynamic planner to decide it's given policy, and therefore, naturally and flexibly enhances the mechanism of the deliberation.

There have been several proposals introducing a planner into a BDI agent ([1, 2, 3]), but they use the planner as a tool that generates plans and provides them to the agents. On the other hand, it is a characteristic point that in our method the dynamic planner works as an effective tool for selecting the action policy of the agent in a dynamic environment. In Sec.4.4, we show that when a robot implemented with this method in our experiment cannot achieve its goal by using the selected plan based on its current action policy, it can change the policy using the dynamic planner and then achieve its goal. Our proposal is effective in that such a property installed in robots is desirable for robots in the real world.

2 BDI AGENTS

A BDI agent[4] is a type of autonomous and rational agent that explicitly has three mental attitudes, beliefs, and desires and intentions (written as B, D and I respectively), and uses their temporal changes in the decision-making process.

When a new goal (desire) arises, a BDI agent selects a usable plan to achieve that goal from the plan library using its belief base ("practical reasoning"), and forms an intention to commit to executing that plan, then adds it to the set of current intentions (active plans). Next, the agent selects a particular intention to execute right now using the belief base (by using a mechanism called "deliberation"), and takes one step to execute it. Subsequently, the agent perceives the environment to update its beliefs, and then updates its intention set (e.g., intentions that have already been achieved are discarded; and if a goal is judged to be impossible to achieve by the current intention for that goal, then that intention is discarded and an alternative intention to achieve the goal is selected[1]). By repeating this sequence of processes as a loop, the agent attempts to achieve its goals.

We use Jason[5], a well-known platform for implementing BDI agents.

3 COOPERATION WITH DYNAMIC PLANNER

In this section, we explain the design of the dynamic planner we propose for use in cooperation with a BDI agent (hereafter called "BDI cooperative dynamic planner"), and explain how it cooperates with the agent.

The BDI cooperative dynamic planner is created by modifying SHOP2[6], a famous hierarchical planner. It uses the planning engine of SHOP2.

Since SHOP2 is designed for static problem solving, when given a goal, it completely decomposes that goal down to a sequence of atomic actions. However, in a dynamic environment, it is impractical to decompose the goal into atomic actions because once the plan is made it may become difficult to proceed with it due to a change in circumstances.

A human being, in a dynamic environment, first makes a rough plan to achieve his/her goal, and when the time comes, he/she decomposes and substantiates the plan more minutely so that it can be directly executed. The BDI cooperative dynamic planner also does the same thing. So, it stops decomposing the plan in the first step of the decomposition process, and accumulates it as a sequence of subgoals. Then, the subgoal at the top of the sequence of subgoals is a goal for the agent, and at this time, the planner decomposes that subgoal into a set of tasks and gives them to the agent who uses them as an action policy for achieving its goals.

If the agent finishes their goal using this policy, it informs the planner, and the planner gives the next subgoal in the sequence to the agent as the next policy. On the other hand, if the agent cannot accomplish the goal using this policy, the planner re-plans under the current condition to create a new action policy and then gives it to the agent.

We implement our planner as a separate program to Jason. The agent running on Jason invokes a sub-process of the planner that stays active until the agent program terminates, and it interacts with the agent using interprocess communications.

[1] Actually, the alternative intention is not selected in this step, but in the next round of a loop.

4 EXAMPLE USING ROBOT

We explain how our proposal is efficient at controlling a robot in the real world using the experiment results in this section.

4.1 Example problem

The example problem for the robot we used in our experiment is to search for treasure in a maze on a grid (Fig.1). Initially, the agent does not have any knowledge about the locations of walls, so each time the agent perceives the existence of a wall, it adds the information about the position of the wall to its belief base. When the robot finds the treasure, it returns back to the initial position. Note that in this experiment, the robot may occasionally collect erroneous information about the positions of walls due to errors in perception caused by the noise of its sensor.

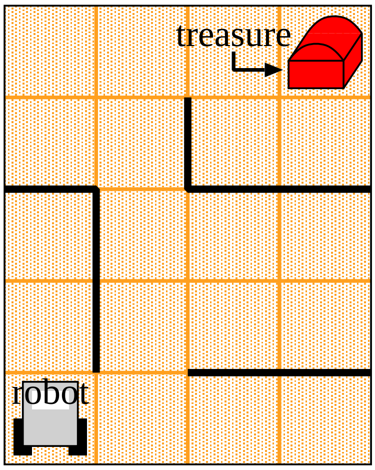

Fig. 1. Map used in our experiment

At first, the robot searches for the treasure while relying on its beliefs about the positions of walls, since it incurs some cost to perceive the walls. However, there are possibilities that the robot is unable to find the treasure due to errors in its beliefs.

If this happens, the robot has to switch to another way of searching while re-perceiving the walls instead of trusting the beliefs about the walls. After that, when the robot finds an unexplored square, it judges that it has escaped the situation of inability to find the treasure, and should switch back to the original way of searching.

4.2 Implementation of atomic actions

The robot we used was a MINDSTORMS NXT developed by the LEGO company. The robot in this experiment is a mobile robot with two front wheels and one rear wheel. It has an ultrasonic sensor in the front to measure the distance to an obstacle (Fig.2).

The NXT fundamentally has only low level commands such as specifying the torque output and receiving an integer signal from the sensor. However, we prepared a higher level of actions, such as "proceed to the next square", "rotate by 90 degrees" and "perceive whether a wall exists", and

The Seventeenth International Symposium on Artificial Life and Robotics 2012 (AROB 17th '12),
B-Con Plaza, Beppu, Oita, Japan, January 19-21, 2012

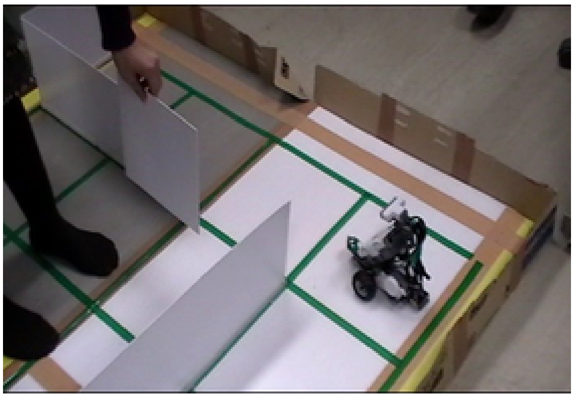

Fig. 2. Schematic layout of our experiment

used them as atomic actions. The merit of this method is that we can separate the low level controls of robots from the plan description of agents. For example, low level robot controls are accompanied by errors due to mechanical inaccuracies with the motors and sensors. If some progress is made with this type of problem, the efficiency of our proposal in this paper improves in conjunction with it, although we do not deal with this topic in this paper.

4.3 Flow of agent program

Let us assume that the agent (robot) has the initial goal of "find the treasure and return to the initial position", and requests an action policy for the subgoal "find treasure" from the planner. The planner creates a "normal search" policy and gives it to the agent. Then, the agent selects a "searching by normal strategy" plan and forms it into an intention.

According to this plan, the agent searches for the treasure while adding (and using) its beliefs about the positions of walls, which is acquired by perception. In this stage, the agent does not repeatedly perceive the places where a wall is believed to exist.

If zero unexplored squares remain, this plan fails. In this case, the agent asks the planner again, and the planner returns a "re-search" action policy. The agent selects a "searching while considering the possibilities of errors with past perceptions" plan, and forms it as a new intention. By following this plan, the agent continues searching while re-perceiving the walls (without relying on the beliefs about the places of walls).

When the agent finds an unexplored square, again it asks the planner for a "normal search" policy. The agent again selects the "searching by normal strategy" plan, makes it an intention, and continues searching in the former way.

After the agent finds the treasure, a "return to the initial position" plan is executed as the next subgoal, which we omit in this paper.

We also omit the actual codes of the agent programs due to space limitations.

4.4 Experimental result

We performed our experiment on a 4 5 grid (Fig.1, 2).

Starting with Fig.1, the agent begins searching using the "normal search" policy described in Sec.4.3.

Meanwhile, to create a situation in which the agent wrongly believes in the existence of a wall, we put an extra wall at a given place in the maze (Fig.3).

Then, the agent continues searching with the erroneous belief in the existence of a wall. When the agent comes that place again, it still believes that there is a wall even after the fake wall has been removed, and does not repeatedly try to perceive it (Fig.4).

The agent goes around all the unexplored squares, and finds that no new routes remain, and thus, it cannot find the treasure. So, the agent asks the planner and switches to the "re-search" policy described in Sec.4.3, and continues searching while re-perceiving in all directions around it (Fig.5).

As a result, the agent finds a new route to the yet unexplored areas (Fig.6). Then, the agent asks the planner, goes back to the "normal search" policy and continues searching until it finds the treasure.

We conducted another experiment in which we place the fake wall on the grid twice. The robot was able to behave properly and find the treasure.

In this regard, we concluded that the robot can deal with the problem of misperception.

5 DISCUSSION

As described in Sec.1, robots in the real world have to change their behaviors according to the various (sometimes unexpected) changes in environments. When an ad-hoc technique, such as the traditional hand-coding method, is used to cope with such problems, there is a tendency for the codes of the plans themselves and the meta-level codes for the switching plans to get mixed up, and the maintainability is then lost.

The BDI agent, as an agent development approach, in comparison with methods such as hand-coding methods, can be regarded as the framework for describing agents using a kind of high-level language. Plans can be described declaratively and in a mutually independent manner, and then explicit codes for switching plans are not necessary. These features are essential for enabling flexible changes in behaviors. Furthermore, the notion of intentions in BDI agents works as a higher-level action decision mechanism and this provides a stable and consistent behavior towards achieving the agent's goals.

In addition, in our method, by leaving the "deliberation" part to the planner, there is no need to procedurally write the deliberation routine, and by only receiving information about the current circumstances from the agent, we can select an

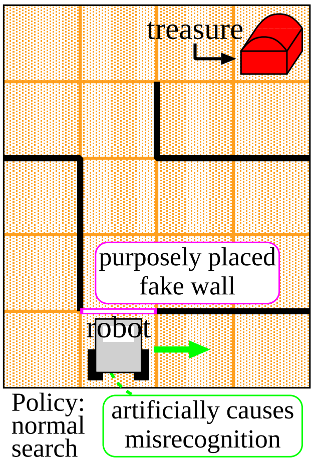

Fig. 3. Producing false recognition of walls

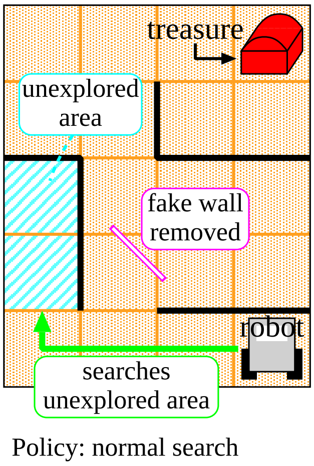

Fig. 4. Continuation of search based on inaccurate belief

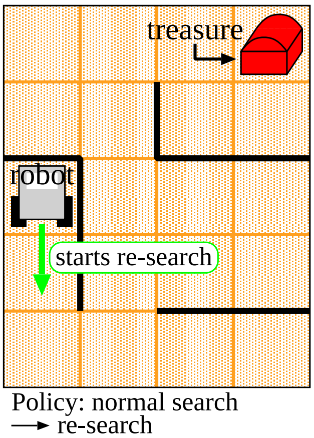

Fig. 5. Being stuck, robot asks planner and switches action policy

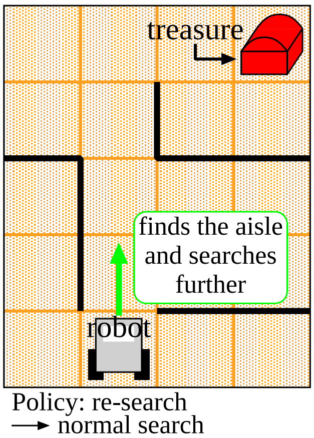

Fig. 6. When unexplored place is found, robot asks planner again, switches policy, and continues searching

appropriate action policy to commit as a plan. Also, when using an efficient planner in large-scale applications, we can expect improvement in the efficiency of selecting plans compared with that from the hand-coding method (though such advantage may be unrealistic in smaller applications such as the experiment discussed in this paper).

Moreover, our method is also a complement to the weakness of Jason as a base of implementation for BDI agents. In Jason, when a plan fails once, the agent can recover by executing a plan for handling that failure, but if the plan for failure fails again, the agent cannot continue to achieve its goal. On the other hand, by using our method, the robot can recover from multiple failures (e.g., misperceptions), as described in Sec.4.4.

Yet another merit of BDI agents is that they have a formalization by using a modal logic named the BDI logic[7], in which not only the demands for the agents but also the behaviors of the agents can be integrally argued. We propose an extension to this by importing the formalization of the planner[8], so there is the future possibility for the formal verification of our method.

6 CONCLUSION

We proposed enhancing the deliberation in BDI agents by introducing a dynamic planner so that an agent can flexibly change its action policy for achieving its goals, and showed that our method is efficient enough for use in robots in the real world through experimentation.

Our future issues include applying this method to a larger task, and introducing the formal verification method introduced in Sec.5.

Abstract: In this paper, we propose adjustment method named *adaptive learning rate considering learning progress* (ALR-P). The learning rate is a meta parameter that balances trade-off between speed and stability of the learning. Conventionally, designer had to manually set up a fixed learning rate. However, it is difficult for learning agent to adapt dynamic environment with a fixed learning rate. ALR-P enables adaptive adjustment of learning rate based on degree of learning progress for every steps. The degree of learning progress is calculated based on TD-error which is a difference of predicted and observed rewards. Only TD-error which can be calculated easily and simply is used in the ALR-P, so it can be applied into any types of reinforcement learning. We confirm effectiveness of ALR-P under a number of dynamic environments through the maze problem in which the environmental changes occurred.

Keywords: reinforcement learning, learning rate, dynamic environment, adaption, degree of learning progress

1 INTRODUCTION

Recently, there are a lot of researches about robotics using the reinforcement learning. The reinforcement learning is a kind of the machine learning which the learning agent learns and acquires appropriate control rules through the trial and error [1]. Because the learning agent acquires the control rules autonomously, for instance, reinforcement learning is often used for autonomous behavior acquisition of robots [2][3].

However, if meta parameters of the learning such as learning rate and the discount rate are inappropriate, the learning agent cannot behave sufficient performance. In general, the optimal value does not exist in these meta parameters, and the designer should adjust them properly according to the target task and progress of learning. In addition, it is difficult to learn appropriately under dynamic environment. When the reinforcement learning is applied to real environmental problem such as robot control, robustness for environmental change and noise should be taken into consideration. However, a lot of conventional methods are based on the premise that environment is static, and do not take environmental change into consideration.

In this paper, we focus on learning rate, which is one of the meta parameters of the reinforcement learning, and propose the dynamic adjusting method for learning rate.

2 REINFORCEMENT LEARNING

The agent learns control rule by repeating a sequence of taking an action based on action-value (Q-value) and receiving a reward. Q-value is predicted value of the total amount of reward that the agent will receive over the future. The reward indicates what is good in an immediate sense.

Softmax method is used for action selection in this paper, which is often used in many reinforcement learning. Softmax method determines selection probabilities of actions based on Q-values for the corresponding actions. Selection probability of action a in state s is shown as $\Pr(a|s)$, and is determined by the following equation.

$$\Pr(a|s) = \frac{\exp(Q(s,a)/\tau)}{\sum_{a' \in A} \exp(Q(s,a')/\tau)}, \tag{1}$$

where A, $Q(s,a)$, and τ show set of actions that the agent can select in the state s, action-value of the action a in the state s, and the temperature, respectively. The agent receives the reward that is the evaluation value of the selected action from the environment.

The agent dynamically updates the action-value function based on the received rewards. In this paper, we use Q( )-learning [4] as learning algorithm. In Q( )-learning, the action-value function is updated according to the following equation.

$$Q(s,a) \leftarrow Q(s,a) + \quad \delta(s,a)e(s,a), \tag{2}$$

where , $\delta(s,a)$, and $e(s,a)$ show the learning rate, the TD-error of action a in the state s, and the eligibility trace, respectively. TD-error is calculated by the following equation.

$$\delta = r + \gamma \max_{a' \in A'} Q(s',a') - Q(s,a), \tag{3}$$

where r, γ, s', and A' show the reward, the discount rate, the following state after the action a, and set of actions that the agent can select in state s', respectively. Roughly, TD-error indicates the difference of the predicted value and the observed value in the state-action pair. Eligibility trace is index which shows whether the updating of the corresponding Q-value is proper or not.

3 LEARNING RATE

As shown in the Equation (2), a learning rate is a meta parameter which determines updating width of action-value function. Generally, in the case of that the learning rate is high, the progress of learning is fast although the learning is not steady. On the other hand, the learning progresses slowly though the learning is steady in the case of that the learning rate is low. This means that the learning rate is a parameter that balances trade-off between speed and stability of the learning.

In this paper, we propose adjustment method named *adaptive learning rate considering learning progress* (ALR-P). ALR-P adjusts learning rate according to each state (or state-action pair) for every step. The learning in the early stage or environment changes should be progressed speedy even if it can be roughly. because the learning agent have to acquire more proper action-value function as soon as possible in that cases. Meanwhile, the learning in the end stage should be progressed more precisely in order to converge action-value on optimal value in high accuracy. From the above things, the learning rate should be adjusted considering the learning progress; the learning rate should be high to value the learning speed in a state that the action-value cannot be correctly estimated, while the one in a state that the action-value can be correctly estimated should be low to value the stability.

4 ALR-P

ALR-P is a method of adjusting learning rate for every step considering learning progress, and we newly propose *degree of learning progress* in order to realize the adjustment of learning rate in this method. In this method, we focus on TD-error which can be thought a difference of predicted and observed rewards. In a state such as early stages of learning and environmental change, TD-error is high because prediction of reward is not proper. On the other hand, in a state such as converging stages of learning, TD-error is low and approaches 0 because prediction of reward is proper. TD-error changes for every steps, since the suitable learning can be not realized if the learning rate is adjusted based on the each change. Thus, we define the expected value of absolute TD-error as the degree of learning progress, and use the degree of learning progress to adjust the learning rate. The degree of learning progress in state s and action a, $d(s, a)$ is defined by the following equation.

$$d(s, a) := E[|\delta(s, a)|]. \tag{4}$$

Table 1. Q( )-learning applying ALR-P

Initialize $Q(s, a)$ arbitrarily for all s, a
Initialize $e(s, a) = 0$ and $d(s, a) = 0$ for all s, a
Repeat (for each episode):
  Initialize s, a
  Repeat (for each step of episode):
    Choose a' from s' using policy derived from Q (e.g., softmax-method)
    $\delta(s, a) \leftarrow r(s, a) + \gamma \max_{a'} Q(s', a') - Q(s, a)$
    $d(s, a) \leftarrow d(s, a) + \omega[|\delta(s, a)| - d(s, a)]$
    If $d(s, a) > d_m(s, a)$:
      $d_m(s, a) \leftarrow d(s, a)$
    $\alpha = d(s, a)/d_m(s, a)$
    $e(s, a) = 1$
    For all s, a:
      $Q(s, a) \leftarrow Q(s, a) + \alpha\delta e(s, a)$
      $e(s, a) \leftarrow \gamma\lambda e(s, a)$
    $s \leftarrow s'$
    until s is terminal

However, to calculate the expected value, it is necessary to save all history of TD-errors in each state-action pair. Since huge calculation memories and costs are needed for calculating the expected value, it is approximated by the following exponential moving average (EMA).

$$d(s, a) \leftarrow d(s, a) + \omega[|\delta(s, a)| - d(s, a)], \tag{5}$$

where ω shows updating width. By using the EMA, only the present TD-error is required to calculate the degree of learning progress, and the maximum $d(s, a)$ in each state-action pair is saved as $d_m(s, a)$. Using the calculated values from Equation (5), the learning rate   is adjusted by the following equation for every steps.

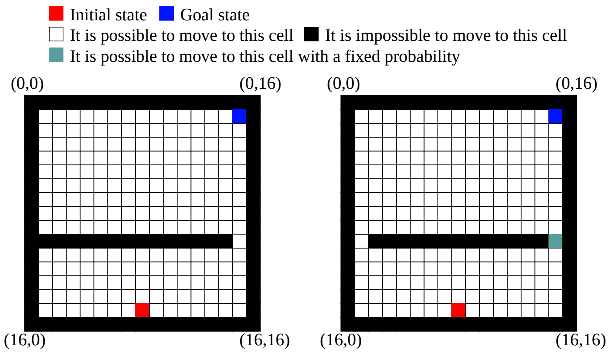
$$= \frac{d(s, a)}{d_m(s, a)}. \tag{6}$$

Because the learning rate is adjusted based on the degree of learning progress that each state-action pair has, so the learning rate can be adjusted according to the each state-action pair.

In ALR-P, only TD-error is used to calculate the degree of learning progress. Because the TD-error is a simple value generally calculated in existing reinforcement learning methods, it is easy to build ALR-P into almost all reinforcement learning methods such as Q-learning, Sarsa, Actor-Critic and so on. Q( )-learning applying ALR-P is shown in Table 1.

5 ADAPTIVE LEARNING EXPERIMENT

We conduct comparative experiments with ALR-P and conventional methods, and verify effectiveness of ALR-P.



(a) Until 100th episode (b) From 101st episode

Fig. 1. Maze problem

5.1 Maze problem with environmental changes

We apply ALR-P to the maze problems (see Fig. 1) in which the environmental changes are occurred. Each cell shows state, and the coordinates are defined as follows: left-uppermost is $(0, 0)$, right-uppermost is $(0, 16)$, left-lowermost is $(16, 0)$, and right-lowermost is $(16, 16)$. An initial state and a goal state are set to $(15, 8)$ located in lower part of the maze and $(1, 15)$ located in upper-right part, respectively. The environmental changes in this experiment is defined as follows; until 100th episode (Fig. 1(b)), agent can reach goal state by passing through $(10, 15)$, from 101th episode (Fig. 1(b)), $(10, 1)$ is opened up along the left side, and $(10, 15)$ changes whether transition is possible or not with a fixed probability for every steps. And we prepared two transition settings, *Setting A*: agent can through the $(10, 15)$ with a possibility 1/7, and *Setting B*: agent can through the cell with a possibility 1/14. In Setting A, the expected value of sum rewards of right side path which contains $(10, 15)$ is higher than one of the left side path which contains $(10, 1)$. On the other hand, in Setting B, the expected values of sum rewards of both side paths are equivalent.

Comparative methods are RRASP-N [5] and the conventional general methods that learning rate is each fixed to 0.3, 0.5, 0.7, and 0.9. RRASP-N is a method to adjust learning rate to minimize square TD-errors. Q( )-learning is used as learning algorithm, and softmax method is used as action selection rule. This experiment consists of 300 episodes, and one episode is that learning agent reaches in goal state or passes over 100 steps. The agent moves to top, bottom, right, or left cell, and receives reward that is -1 in a step.

5.2 Experimental results

5.2.1 Transition of sum rewards

The above-mentioned experiments were conducted 100 times for the each method. The results shown in Fig. 2 and Fig. 3 indicate that the transition of sum rewards in the Setting A and Setting B, respectively. In Setting A, as comparing the results of the conventional methods that learning rate is each fixed, it was confirmed that advantage by magnitude relation of learning rate is reversed before and after environmental changes. Also in Setting B, there is no conventional method that always keeps advantage without differences of learning rate. Therefore, high learning performance could not be behaved with a stationary learning rate in this problem.

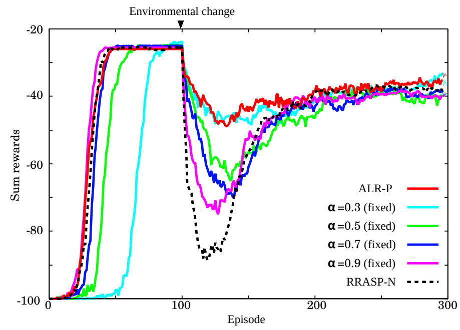


Fig. 2. Transition of sum rewards in the Setting A

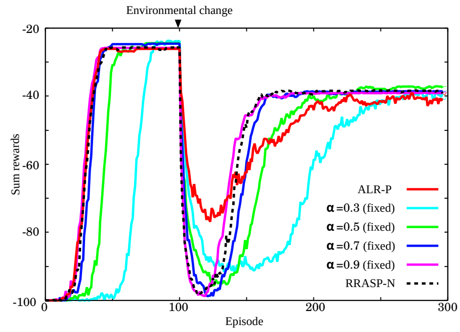

Fig. 3. Transition of sum rewards in the Setting B

From Fig. 2 and Fig. 3, we confirmed that ALR-P behaved high performance, irrespective of environmental changes. Before the environmental changes, ALR-P converged learning fast. After the environmental changes, ALR-P behaved relatively high performance, and progresses learning without greatly reducing sum rewards even though immediately after the environmental changes. On the other hand, RRASP-N was reduced sum rewards greatly in the both settings.

5.2.2 Transition of learning rate

Fig. 4 shows an example of transition of learning rate in state-action pair that state is $(11, 15)$ and action is moving to up. From this figure, we confirm that after environmental changes learning rate was adjusted high again. Because the location of state $(11, 15)$ was near the state in which environmental changes occurred, it is thought that the state was profoundly affected by the environmental changes. ALR-P

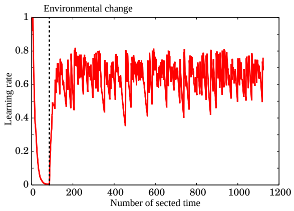

Fig. 4. Transition of learning rate in state-action pair that state is $(11, 15)$ and action is moving to up

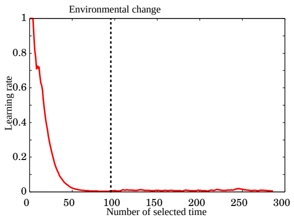

Fig. 5. Transition of learning rate in state-action pair that state is $(15, 8)$ and action is moving to right

Table 2. Success rate of the task and selection path at success episode after environmental changes in the Setting A

Learning rate	Success rate (%)	Selection rate of $(10, 1)$ (%)	Selection rate of $(10, 15)$ (%)
ALR-P	94.25	16.29	83.51
$\alpha = 0.3$ (fixed)	86.08	8.49	91.51
$\alpha = 0.5$ (fixed)	82.59	31.62	68.38
$\alpha = 0.7$ (fixed)	84.43	56.12	43.88
$\alpha = 0.9$ (fixed)	85.16	67.58	32.42
RRASP-N	83.08	84.38	15.62

Table 3. Success rate of the task and selection path at success episode after environmental changes in the Setting B

Learning rate	Success rate (%)	Selection rate of $(10, 1)$ (%)	Selection rate of $(10, 15)$ (%)
ALR-P	83.20	64.67	35.33
$\alpha = 0.3$ (fixed)	62.51	66.06	33.94
$\alpha = 0.5$ (fixed)	75.84	86.26	13.74
$\alpha = 0.7$ (fixed)	81.13	94.99	5.01
$\alpha = 0.9$ (fixed)	84.45	97.21	2.79
RRASP-N	83.08	96.83	3.17

could promote relearning by adjustment of the learning rate according to the variation of TD-error.

Fig. 5 shows an example of transition of learning rate in state-action pair that state is initial state $(15, 8)$ and action is moving to right. From this figure, we confirm that the learning rate was not high even though it was after the environmental changes. Because the location of state $(15, 8)$ was far from the state in which environmental changes occurred, it is thought that the state is not seriously affected by the environmental changes. From these results, it was confirmed that ALR-P could adjust learning rate to appropriate value on each state.

5.2.3 Success rate of task

The results shown in Table 2 and Table 3 indicate that success rate of the task and selection path at success episode after environmental changes in the Setting A and Setting B, respectively. From these tables, we confirm that success rate of ALR-P is relatively higher than other methods in the both settings. The results suggest that ALR-P enables adaptive learning under dynamic environment and has general versatility.

From the tables, we confirmed that ALR-P showed the relatively higher selection rate of $(10, 15)$ than other methods. In Setting B, although expected values of sum rewards of right and left side paths are equivalent, the right side path can be the shortest. Therefore, it can be said that ALR-P not only maintains high success rate, but also searches shorter path.

When RRASP-N is applied, selection rate of $(10, 1)$ is relatively higher than other methods. Thus, it is thought that RRASP-N maintains high success rate by selecting left side path in which environmental change does not occur.

6 CONCLUSION

In this paper, we propose adjustment method named adaptive learning rate considering learning progress (ALR-P). We confirmed that learning agent can adapt to dynamic environment by using ALR-P through maze problem with environmental changes.

For example, in robotic control of humanoids under real world, it is necessary to consider risk such as tumble. ALR-P which can adapt appropriately to dynamic environment is expected to decrease influence of breakdown caused by abrasion of joint, disturbance and so on.

Abstract: Engineers and researchers are paying more attention to reinforcement learning (RL) as a key technique for realizing adaptive and autonomous decentralized systems. In general, however, it is not easy to put RL into practical use. Our approach mainly deals with the problem of designing state and action spaces. Previously, an adaptive state space construction method which is called a "state space filter" and an adaptive action space construction method which is called "switching RL," have been proposed after the other space has been fixed.
In this paper, we reconstitute these two construction methods as one method by treating the former method and the latter method as a combined method for mimicking an infant's perceptual and motor developments. Then the proposed method is based on introducing and referring to "entropy." In addition, a computational experiment was conducted using a so-called "robot navigation problem" with three-dimentional continuous state space and two-dimensional continuous action space. As a result, the validity of the proposed method has been confirmed.

Keywords: reinforcement learning, adaptive space co-construction, state space design, action space design, entropy

1 INTRODUCTION

Engineers and researchers are paying more attention to reinforcement learning (RL)[1] as a key technique in developing autonomous systems. In general, however, it is not easy to put RL to practical use. Such issues as satisfying the requirements of learning speed, resolving the perceptual aliasing problem, and designing reasonable state and action spaces for an agent, etc., must be resolved. Our approach mainly deals with the problem of designing state and action spaces. By designing suitable state and action spaces adaptively, it can be expected that the other two problems will be resolved simultaneously. Here, the problem of designing state and action spaces involves the following two requirements: (i) to keep the characteristics of the original search space as much as possible in order to seek strategies that lie close to the optimal, and (ii) to reduce the search space as much as possible in order to expedite the learning process. In general, these requirements are in conflict.

Recently an adaptive state space construction method which is called a "state space filter[3]," and an adaptive action space construction method which is called a "switching learning system[4]," have been proposed after the other space has been fixed. Here, we reconstitute these two construction methods as one method by treating them as a combined method for mimicking an infant's perceptual and motor developments The proposed method is to construct state and action spaces adaptively by introducing and referring to the "entropy" as an index of both necessity for the division of the state space in the state and sufficiency for the number of learning opportunities in the state. In addition, a computational experiment was conducted using a so-called "robot navigation problem" with three-dimentional continuous state space and two-dimensional continuous action space.

2 TYPICAL RL METHODS

2.1 Q-learning

Q-learning works by calculating the quality of a state-action combination, namely the Q-value, that gives the expected utility of performing a given action in a given state. By performing an action $a \in \boldsymbol{\mathcal{A}}_{\mathrm{Q}}$, where $\boldsymbol{\mathcal{A}}_{\mathrm{Q}} \subset \boldsymbol{\mathcal{A}}$ is the set of available actions in Q-learning and $\boldsymbol{\mathcal{A}}$ is the action space of the agent, the agent can move from state to state. Each state provides the agent with a reward r. The goal of agent is to maximize its total reward.

The Q-value is updated according to the following formula, when the agent is provided with the reward:

$$Q(s(t\text{-}1), a(t\text{-}1)) \leftarrow Q(s(t\text{-}1), a(t\text{-}1)) + \alpha_{\mathrm{Q}}\{r(t\text{-}1) + \gamma \max_{b \in \boldsymbol{\mathcal{A}}_{\mathrm{Q}}} Q(s(t), b) - Q(s(t\text{-}1), a(t\text{-}1))\} \quad (1)$$

where $Q(s(t\text{-}1), a(t\text{-}1))$ is the Q-value for the state and the action at the time step t-1, $\alpha_{\mathrm{Q}} \in [0, 1]$ is the learning rate of

Q-learning, $\gamma \in [0,1]$ is the discount factor.

The agent selects an action according to the stochastic policy $\pi(a|s)$, which is based on the Q-value. $\pi(a|s)$ specifies the probabilities of taking each action a in each state s. Boltzmann selection, which is one of the typical actionselection methods, is used in this research. Therefore, the policy $\pi(a|s)$ is calculated as

$$\pi(a|s) = \frac{\exp(Q(s,a)/\tau)}{\sum_{b\in\mathcal{A}} \exp(Q(s,b)/\tau)} \tag{2}$$

where τ is a positive parameter labeled temperature.

2.2 Actor-Critic

Actor-critic methods have a separate memory structure in order to represent the policy explicitly independently of the value function. The policy structure is called the "actor," which selects the actions, and the estimated value function is called the "critic," which criticizes the actions made by the actor. The critic is a state-value function. After each action selection, the critic evaluates the new state to determine whether things have gone better or worse than expected. That evaluation is TD-error:

$$\delta(t\text{-}1) = r(t\text{-}1) + \gamma V(s(t)) - V(s(t\text{-}1)) \tag{3}$$

where $V(s)$ is the state value.

Then, $V(s(t\text{-}1))$ is updated according to Eq. 4 in the critic based on this $\delta(t\text{-}1)$. In parallel, it is updated for the stochastic policy $\pi(a|s)$, in the actor.

$$V(s(t\text{-}1)) \leftarrow V(s(t\text{-}1)) + \alpha_{\mathrm{C}}\delta(t\text{-}1) \tag{4}$$

where $\alpha_{\mathrm{C}} \in [0,1]$ is the learning rate of the critic.

It is typical for the normal distribution, shown in Eq. 5, to be used as the stochastic policy in the actor, when actor-critic is applied to a continuous action space[2].

In this case, both the mean $\mu(s)$ and the standard error of the mean $\sigma(s)$ about the normal distribution are calculated using TD-error $\delta(t\text{-}1)$ in the actor, as in Eqs. 6 and 7.

$$\pi(a|s) = \frac{1}{\sigma(s)\sqrt{2\pi}} \exp(\frac{-(a-\mu(s))^2}{2\sigma(s)^2}) \tag{5}$$

$$\mu(s(t\text{-}1)) \leftarrow \mu(s(t\text{-}1)) + \alpha_\mu \delta(t\text{-}1)(a(t\text{-}1) - \mu(s(t\text{-}1))) \tag{6}$$

$$\begin{aligned}\sigma(s(t\text{-}1)) \;\leftarrow\; & \sigma(s(t\text{-}1)) \\ & + \alpha_\sigma \delta(t\text{-}1)((a(t\text{-}1) - \mu(s(t\text{-}1)))^2 - \sigma(s(t\text{-}1))^2)\end{aligned} \tag{7}$$

where $\alpha_\mu \in [0,1], \alpha_\sigma \in [0,1]$ are the learning rate of the mean and the standard error of the mean, respectively. Here, if Eq. 7 is used directly, the standard error could be 0 or a negative value. Therefore it is necessary when setting the standard error to be creative and to specify the range, etc.

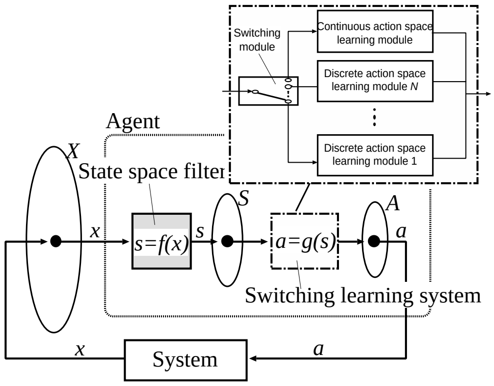

Fig. 1. Proposed development RL model

3 DEVELOPING RL

3.1 Outline of a Computational Model

In this section, we propose developing an RL model to mimic the processes of an infant's perceptual and motor developments. The proposed model is constructed by "state space filter[3]" to mimic the process of perceptual development in which perceptual differentiation progresses as the infant becomes older and more experienced, and a "switching learning system[4]" to mimic the process of motor development in which gross motor skills develop before fine motor skills, as shown in Fig. 1.

This model mimics the process of perceptual development by differentiating the state space gradually from the undifferentiated state space. In parallel, this model also mimics the process of motor development by switching discrete action space learning modules (hereafter called "DA modules") from a more coarse-grained DA module to a more fine-grained DA module, and finally switching to a continuous action space learning module (hereafter called a "CA module").

3.2 State and Action Spaces Construction Method

3.2.1 Basic Idea

A variety of methods can be considered to acquire the state space filter and the switching learning module. Here, we propose a method based on introducing and referring to the entropy, which is defined by action selection probability distributions in a state, and the number of learning opportunities in the state. It is expected that the proposed method (i) is able to learn in parallel the state space filter and the switching learning system, and (ii) does not required specific RL methods for the learning module.

The entropy of action selection probability distributions using Boltzmann selection in a state $H_{\mathrm{D}}(s)$ is defined by

$$H(s) = -(1/\log|\mathcal{A}_{\mathrm{D}}|) \sum_{a\in\mathcal{A}_{\mathrm{D}}} \pi(a|s)\log\pi(a|s) \tag{8}$$

where $\mathcal{A}_{\mathrm{D}}$ is the action space and $|\mathcal{A}_{\mathrm{D}}|$ is the number of available actions of the DA module.

The state space filter is adjusted and the learning module is switched by treating this entropy $H(s)$ as an index of the necessity of division for an inner state s and the action space. In parallel, the learning module is switched by treating this entropy $H(s)$ as an index of sufficiency for the number of learning opportunities in the state.

If the entropy does not get smaller despite the learning module having had a sufficient number of learning opportunities in the inner state, then the state space filter is adjusted by dividing the inner state, and the learning module is switched to a more fine-grained one. In contrast, if the entropy gets small regardless of the number of learning opportunities, the learning module is switched to the CA module because the number of learning opportunities is sufficient.

In this article, Q-learning and actor-critic are applied to the DA module and the CA module, respectively. The learning module is switched in the order of Q-learning with an action space divided evenly into $n, 2n, \cdots, 2^{(N-1)}n$, and finally ending with actor-critic, where N is the number of DA modules.

3.2.2 Adjustment of State Space Filter

If $L(s) > \theta_{\mathrm{L}}$ and $H(s) > \theta_{\mathrm{H}}$, where $L(s)$ is the number of learning opportunities in s, θ_L is a threshold value of the number of learning opportunities, θ_{H} is a threshold value of the entropy, and θ_{L} is set at a sufficiently large number, then the state space filter is adjusted by dividing the range of the input state mapped to the inner state s into two parts for each dimension, and mapping each part to a different inner state. Simultaneously, the learning module is switched. Through this operation, the size of the inner state space increases by $(2^M - 1)$ after being divided, where M is the number of dimensions. Also note that the values of the new $2M$ inner states are the value of the inner state before it was divided.

In addition, after the learning module is switched to the CA module, if $L(s) > \theta_{\mathrm{L}}$, then the state space filter is adjusted by dividing the inner state so that it is more fine-grained.

3.2.3 Switching of Learning Module

If $H(s) > \theta_{\mathrm{H}}$, then the learning module is switched to the CA module because the number of learning opportunities is then sufficient. In the procedure to switch controllers, the result of Q-learning is succeeded by actor-critic and the following procedure is carried out. 1. The state value of the critic, $V(s)$, is initialized by

$$V(s) = \sum_{a \in \boldsymbol{\mathcal{A}}_{\mathrm{Q}}} \pi(a|s) \cdot Q(s,a) \tag{9}$$

2. The normal probability distribution used by the actor is calculated by

$$\mu(s) = \arg\max_{a \in \boldsymbol{\mathcal{A}}_{\mathrm{Q}}} Q(s,a), \tag{10}$$

$$\sigma(s) = |A_{\mathrm{Q}}(\arg\max_{a \in \boldsymbol{\mathcal{A}}_{\mathrm{Q}}} Q(s,a))|/6 \tag{11}$$

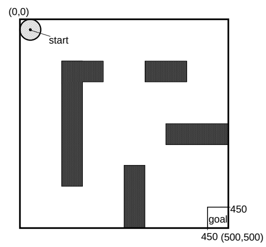

Fig. 2. Robot navigation problem

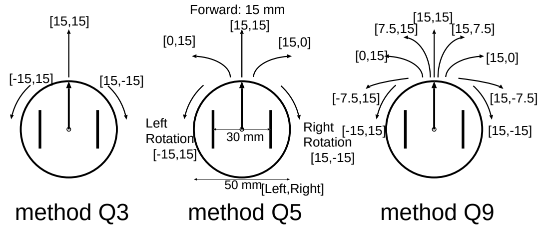

Fig. 3. Available actions of 3 Q-learning methods

where $|A_{\mathrm{Q}}(i)|$ is the range of the action space which represents action i of Q-learning.

If $L(s) > \theta_L$ and $H(s) > \theta_{\mathrm{H}}$, then the learning module is switched to more fine-grained DA module, and finally ends with the CA module. Simultaneously, the state space filter is adjusted.

The Q-values of newly added actions a_i at this time are set according to the following formula :

$$Q(s,i) = \max_{j \in i-1, i+1} Q(s,j) \tag{12}$$

where action $i-1$ and $i+1$ are adjacent to action i. This formula is set in consideration of a more efficient search as well as the idea of the optimistic initial values.

4 COMPUTATIONAL EXAMPLE

4.1 Robot Navigation Problem

The proposed method is applied to a so-called "robot navigation problem" navigating a learning agent from a starting point to a goal area in a continuous state space, as shown in Fig. 2.

Here, the agent has a circular shape (diameter 50 mm), and the continuous space is 500 mm$\times 500$ mm bounded by the external wall, with internal walls as shown in black. The agent can observe the center of its own position and its own direction: $(x_{\mathrm{A}}, y_{\mathrm{A}}, \theta_{\mathrm{A}})$ as the input. The agent has two wheels and can move in any direction, i.e., it can decide right-and-left wheel rotation rates (mm/step): $(\omega_{\mathrm{L}} \in [-15.0, 15.0], \omega_{\mathrm{R}} \in [-15.0, 15.0])$ as the output.

The positive reinforcement signal $r_t = 10$ (reward) is given to the agent only when the center of the agent arrives in the goal area, and the reinforcement signal is $r_t = 0$ at all other steps. The period from when the agent is located at the starting point to when the agent is given a reward, or $100,000$ steps pass away, labeled as 1 episode, is repeated.

4.2 Comparison with adaptive methods

We have confirmed that a combined method of state space filter and switching learning system (hereafter called the "FS" method) shows a better performance than three Q-learning methods where the number of actions is designed to be 3, 5, and 9 (hereafter called the "Q3," "Q5," and "Q9" methods, respectively), and an actor-critic method (hereafter called the "AC" method)with the state space divided evenly into $5 \times 5 \times 8$, $10 \times 10 \times 16$, and $20 \times 20 \times 32$ in this task. Fig. 3 shows the wheel rotation rates on each actions of three Q-learning methods.

In this section, the FS method is compared with three methods using the switching learning system with the state space divided evenly into $5 \times 5 \times 8$, $10 \times 10 \times 16$, and $20 \times 20 \times 32$ (hereafter called the "S5," "S10," and "S20" methods, respectively), and three Q-learning methods, the Q3, Q5, and Q9 methods, using the state space filter (hereafter called the "FQ3," "FQ5," and "FQ9," methods, respectively). Here, an initial state space filter is designed that divides the state space evenly into $5 \times 5 \times 8$ spaces, and the switching learning system is constructed by four learning modules: the "Q3," "Q5," "Q9," and "AC" methods.

All initial Q-values are set at 5.0 as the optimistic initial values[1] for Q-learning methods and the range of $\sigma(x)$ is set at $[0.001, 30.0]$ for the AC method. Here, the maximum limit of $\sigma(x)$ is set so that it becomes the size of the action space: 30.0. Further, the adjustment of the state space filter is assumed until the third attempt in all inner states because it is impossible to evaluate sufficiency for division of the state space.

Computer experiments have been carried out with the parameters shown in Table 1. Here, θ_{H} was set to about 0.359, the maximal value of the entropy when the highest selection probability for one action is 0.9, θ_{L} was set to a large enough number.

The average number of steps required to accomplish the task was observed during learning over 20 simulations with different methods, as described in Fig. 4. The average size of the inner state space was observed during learning over 20 simulations with different methods, as described in Fig. 5.

It can be seen from Fig. 4 that, (1) the FS method showed a worse performance than the FQ3, FQ5, FQ9 and S10 methods with regard to the learning speed, but a better performance than any other methods with regard to the control rule obtained. (2) the S5 method couldn't acquire any proper control rule.

Table 1. Parameters for experiments

Parameter	Value	Parameter	Value
$\alpha_{\mathrm{Q}}, \alpha_{\mathrm{C}}, \alpha_{\mu}, \alpha_{\sigma}$	0.1	γ	0.9
θ_{H}	0.4	τ	0.1
θ_{L}	1000		

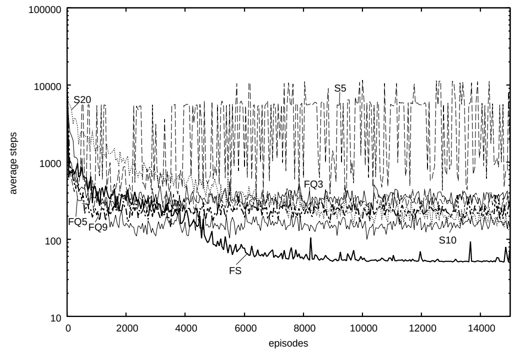

Fig. 4. Required steps

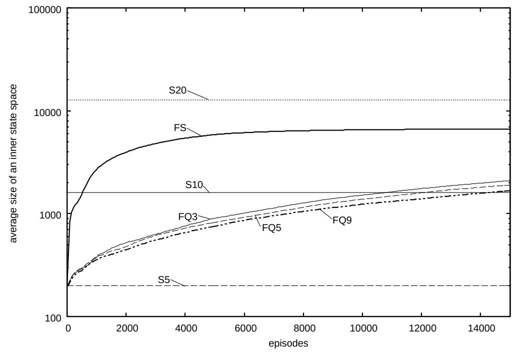

Fig. 5. Size of the inner state space

It can be seen from Fig. 5 that, (1) the FS method is smaller than the S20 method, but larger than any other method except the S20, (2) and is not growing since about 5,000 episode with regard to the size of the inner state space.

Therefore, we have confirmed that the FS method demonstrates better performances than any other method for the robot navigation problem.

5 CONCLUSION

In order to design suitable state and action spaces adaptively, we have proposed the developing RL model, and the state and action spaces co-construction method referring to "entropy." Then, with a computational experiment we confirmed that the combined method of the state space filter and the switching learning system shows better performances than any other method for the robot navigation problem with continuous state and action space.

Our future projects include considering more complicated problems and real-world problems, etc.

Abstract: Multi-stage decision making (MSDM) problems often include changes in practical situations. For example travelling time of a path changes in the path selection problems in road networks. The changes cause risks in adopting solutions to MSDM problems. Therefore, we propose a method for solving MSDM problems considering risks. Reinforcement learning (RL) is adopted as a method for solving those problems, and stochastic changes of action sets are treated. It is necessary to evaluate risks besed on subjective views of decision makers (DMs) because the risk evaluation is by nature subjective and depends on DMs. Therefore, we develop an RL approach to MSDM problems with stochastic changes in sets of alternative actions, which uses new method for evaluating risks of the changes. The effectiveness of the method is illustrated with a road network path selection problem.

Keywords: Multi-stage desicion making, Risk assessment, Subjective occurrence probability, Reinforcement learning

1 INTRODUCTION

In practical situations, there are various Multi-stage decision making (MSDM) problems with changes. For example, in the path selection problem of road network, travelling time of paths changes. There are several optimization methods to solve MSDM problems without changes. In this paper, we adopt Reinforcement Learning (RL), which needs no models of problems for solving MSDM problems [1], and modify RL to MSDM problems with changes.

When MSDM problems include changes, we have to consider risks caused by the changes. In general, risks are evaluated by the occurrence probabilities of changes and costs incurred by the changes. Here, a cost represents the degree of undesirable effect; it does not necessarily indicate an amount of money. In RL, effects of stochastic events are originally evaluated by the expectation, but risks evaluated by the expectation may not fit subjective views of decision makers (DMs). Therefore, a method is necessary for evaluating risk that can incorporate DM's subjective views.

An RL method was reported for solving MSDM problems with changes of state transition probabilities [2] and RL methods for solving MSDM problems with changes of rewards [3, 4]. The former considers states called error states, which are undesirable or dangerous states, and defines risks as probabilities that the agent enters error states. The latter defines risks as variances of rewards or worst-cases of reward changes. Those adopt a weighted sum of expectations of rewards and costs incurred by changes as value functions. In those methods, adjustments of weights reflect DM's subjective views. The determination of the weight values cannot be done intuitively and therefore is not easy. In contrast to those two types of changes, there are also changes of action sets in practical problems. Therefore this type of changes is dealt with in this paper.

The above-mentioned methods need estimates of costs incurred by changes. However, for changes of action sets, estimates of costs incurred by changes cannot be obtained until the learning converges sufficiently, because costs are only evaluated by the difference between the value of the optimal action and the value of the suboptimal action. Therefore, we focus on probabilities at which action sets change, and propose a new method for evaluating risks with DM's subjective views in the form that can fit the RL framework. We assume that probability distributions are known as also assumed in the above-mentioned articles [2, 3, 4].

2 REINFORCEMENT LEARNING

RL is a method for getting optimal action selection policy automatically based on trial-and-error in order to solve complex or unknown problems. Signals used in RL are denoted as follows:

- discrete-time : $t\ (= 0, 1, 2, \ldots)$,
- state of environment at time t : $s_t \in S$,
- action taken by agent at time t : $a_t \in A_{s_t}$,
- reward obtained from environment at time t : r_t,
- policy of agent : $\pi(s, a)$.

In RL, learning is performed by the interaction between the environment and the agent as shown in Fig.1.

First, after the agent takes action a_t at time t, the state s_t transitions to s_{t+1} at next time $t+1$ by the action a_t. As a result, the agent gets the reward r_{t+1}. Second, the agent updates its own policy π, that is strategy of action selection, based on the obtained reward. The agent takes action based on the policy.

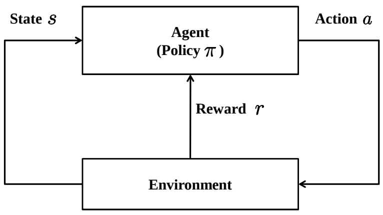

Fig. 1. The interaction between the environment and the agent.

In Fig.1, one cycle is called one step, and sequences of actions and state transitions from starting states to termination states are called an episode.

Because the reward is the only criterion in RL, the agent evaluates merits of actions and states based on the rewards, and those merits are called the values. The action value function is defined as

$$Q^{\pi}(s,a) = E\left[\sum_{k=0}^{\infty} \gamma^k r_{t+1+k} \mid s_t = s, a_t = a, \pi\right]. \quad (1)$$

The equation (1) represents the value of the action $a_t = a$ in the state $s_t = s$ at the time t under the condition that the action is selected by the policy π at time $t+1$ and thereafter. The value is expressed by the expectation of weighted sum of rewards obtained from time $t+1$ to the future.

3 PROPOSED METHOD

3.1 General Problem Setting

We assume Markov decision processes (MDPs). The MDPs include changes of action sets: some of alternative actions become unavailable at certain probabilities in some states. Moreover, there are dependences between occurrences of a number of action changes, and those dependences are described by the conditional probabilities. In this paper, we assume that all of those probabilities are known. Since probabilities that new unknown alternative actions appear are explicitly zero, they do not appear.

3.2 Subjective Occurrence Probability

Risks are evaluated, in general, by occurrence probabilities of changes and costs incurred by changes. When the optimal action becomes unavailable by the change, we have to use a suboptimal action. Therefore, costs are described by difference between the value of the optimal action and the value of the suboptimal action. Occurrence probabilities of changes are assumed to be known, but the costs cannot be obtained until the learning converges sufficiently. Therefore, we consider risk evaluations based on only occurrence probabilities.

Now, consider people who decide to take an umbrella or not after knowing the rainfall forecast. Some people take an umbrella if the rainfall probability is 50 %, but others do not take an umbrella even if the rainfall probability is 50 %. It means that people who take an umbrella consider that it may rain if the rainfall probability is equal to or higher than 50 %, and people who do not take an umbrella consider that it will not rain even if rainfall probability is 50 %. In this way, interpretations of occurrence probabilities vary from person to person.

In this paper, we propose a function $F(p)$ below that can approximate the relationship between objective occurrence probability p and subjective occurrence probability P, and use P as subjective evaluations of the risks,

$$P = F(p) = \frac{1+\exp(\frac{\tau-1}{\sigma})}{\exp(\frac{\tau}{\sigma}) - \exp(\frac{\tau-1}{\sigma})} \frac{\exp(\frac{\tau}{\sigma}) - \exp(\frac{\tau-p}{\sigma})}{1+\exp(\frac{\tau-p}{\sigma})}, \quad (2)$$

where $\tau (0 \leq \tau \leq 1)$ and $\sigma (\sigma \leq 1)$ are parameters reflecting DM's subjective views. Because $F(\tau) = 0.5$ holds, DMs consider that changes will likely to occur if $p \geq \tau$ and consider that chages will not likely to occur if $p < \tau$, that is, the parameter τ means the threshold value. The parameter σ controls the gradient around the threshold value. The curves of equation(2) with various parameter are shown in Fig.2.

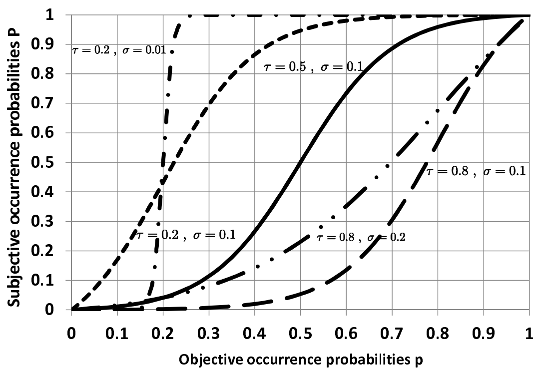

Fig. 2. Subjective occurrence probabilities for objective occurrence probabilities (Function $F(p)$).

3.3 The Compatibility Between the Learning Algorithm and the Risk Evaluation

The value of an action that may become unavailable should be reduced based on DM's subjective interpretations of occurrence probabilities. We multiply the value by a factor $1 - P_t$, where P_t is the subjective probability that the action at time t, a_t becomes unavailable, that is, if the DM interprets that the action will not be available at a high subjective probability ($P_t \simeq 1$), its value is reduced almost to zero. Therefore, the updating equation of Q is defined as

$$Q(s_t, a_t) \leftarrow (1-\alpha)Q(s_t, a_t) \\ +\alpha(1-P_t)\{r_{t+1} + \gamma \max_a Q(s_{t+1}, a)\}. \quad (3)$$

This update formula converges to

$$(1-P_t)\sum_{t=0}^{\infty}(\prod_{j=1}^{k}\gamma(1-P_{t+j}))r_{t+1+k}$$

which is a sum of rewards discounted by not only γ but also $1-P_{t+j}$.

The objective occurrence probabilities p are assumed to be known. But, even if the agent estimates occurrence probabilities, this method is efficient because the convergence of objective occurrence probability estimates is faster than the convergence of value functions.

3.4 Dependence between changes

If there are dependences between changes of action sets for different states, whether a certain action was available or not affects occurrence of changes of other actions which depend on that action. Once we know that a change C_1 has occurred then we can know whether a change C_2 that depends on change C_1 occurs or not with more confidence, i.e. with probability close to 1 or 0. Therefore, when availability of a certain action is known in an episode, we define augmented states x as states including the information. A binary variable f_i is defined which represents the availability of action i: if action i is unavailable, $f_i = 0$, and if action i is available, $f_i = 1$. A vector f is defined as the vector composed of all relevant f_i, and x is defined as $x = \begin{bmatrix} f \\ s \end{bmatrix}$.

Action values $\bar{Q}$ based on augmented states x are updated by

$$\bar{Q}(x_t, a_t) \leftarrow (1-\alpha)\bar{Q}(x_t, a_t) \\ +\alpha(1-P)\{r_{t+1} + \gamma \max_a \bar{Q}(x_{t+1}, a)\}. \quad (4)$$

In each episode, at first, the agent selects actions based on Q. When availability of a certain action that has influences on changes of other actions is known, the agent selects actions based on $\bar{Q}$ until that episode ends. It means that the agent modifies the policy by using real time information.

4 SIMULATIONS

4.1 Problem Setting

We use an example road network shown in Fig.3, where the branches represent road sections and the nodes represent intersections.

In Fig.3, a number in a node is a state number, and a number at the side of a branch is reward obtained by selecting that branch as an action. A large reward is desirable. The starting state is state 0 and the termination state is state 22. $E_{i,j}$ represent an event that an action $a_{i,j}$ moving from node i to node j becomes unavailable.

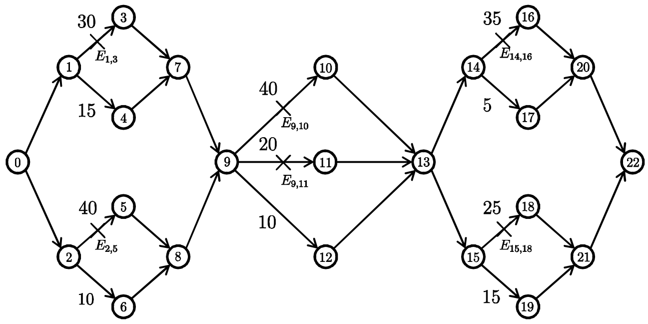

Fig. 3. An example road network.

In branches whose rewards are not explicitly shown, the rewards are all 0 to simplify the problem because those branches are not affected by changes.

Moreover, we assume dependences only between changes of actions selectable in an episode.

For example, we assume that there is dependence between $E_{1,3}$ and any changes except $E_{2,5}$ because the agent can select any changeable actions except $a_{2,5}$ after selecting $a_{1,3}$, but we assume no dependence between $E_{1,3}$ and $E_{2,5}$ since the agent cannot select $a_{2,5}$ after selecting $a_{1,3}$.

4.2 Parameter Setting

Occurrence probabilities of each change in Fig.3 are defined as shown in Table1.

Table 1. Occurrence probabilities.

Probabilities	Conditional event E				
	None	$E_{1,3}$	$E_{2,5}$	$E_{9,10}$	$E_{9,11}$
$P(E_{1,3} \mid E)$	0.35	-	-	-	-
$P(E_{2,5} \mid E)$	0.65	-	-	-	-
$P(E_{9,10} \mid E)$	0.65	0.8	0.2	-	-
$P(E_{9,11} \mid E)$	0.35	0.8	0.8	0.65	-
$P(E_{14,16} \mid E)$	0.65	0.8	0.5	0.2	0.5
$P(E_{15,18} \mid E)$	0.35	0.8	0.5	0.8	0.5

Conditional probabilities given two events, e.g. the conditional probability of $E_{i,j}$ given $E_{k,l}$ and $E_{m,n}$, are not shown in Table1, but we assume that all of these conditional probabilities are 0.5.

We do not treat conditional probabilities given three or more events, and this reason is explained later.

The agent only knows whether actions subject to changes are available or not after trying to take those actions. For example, the occurrence of event $E_{1,3}$ is known after the agent selects an action $a_{1,3}$.

Parameters used in simulations are shown below:
- the number of episode: $10,000,000$,
- the learning rate α: 0.1,
- the discount factor γ: 0.9,
- the method for action selection: $\epsilon-$greedy (ϵ is decreased from 0.5 to 0.05 step by step).

We perform simulations with different parameters in $F(p)$ namely DMs with different subjective interpretation as below:

DM(a) $\tau = 0.5, \sigma = 0.1$,
DM(b) $\tau = 0.3, \sigma = 0.1$,
DM(c) $\tau = 0.5, \sigma = 1$.

Parameter settings of DM(a) and DM(b) correspond to DMs considering that changes are likely to happen when the objective occurrence probabilities equal to or higher than 0.5 and 0.3, respectively because τ is the parameter adjusting threshold values, that is, DM(b) takes more risks than DM(a). DM(a) and DM(c) have the same τ value, but different σ values. DM(c) has gentler slope and therefore does not consider the change is likely to happen until its objective probability well exceeds 0.5.

4.3 Results

Optimal routes based on learned action value functions are shown as belows. ($E_{1,3}$) indicates that the shown route is the optimal route when the occurrence of $E_{1,3}$ is known by selecting $a_{1,3}$.

DM(a) $\tau = 0.5, \sigma = 0.1$
0-1-3-7-9-11-13-15-18-21-22
0-1-4-7-9-12-13-15-19-21-22 ($E_{1,3}$)
0-1-3-7-9-12-13-14-16-20-22 ($E_{9,11}$)
0-1-4-7-9-12-13-14-16-20-22 ($E_{1,3} \cap E_{9,10}$,$E_{1,3} \cap E_{9,11}$)

DM(b) $\tau = 0.3, \sigma = 0.1$
0-1-4-7-9-12-13-15-19-21-22
0-1-4-7-9-12-13-15-19-21-22 ($E_{1,3}, E_{9,11}$)
0-1-4-7-9-12-13-14-16-20-22 ($E_{9,10}$)
0-1-4-7-9-12-13-15-19-21-22 (($E_{1,3} \cap E_{9,10}) \cup (E_{1,3} \cap E_{9,11}$))

DM(c) $\tau = 0.5, \sigma = 1$
0-1-4-7-9-12-13-15-18-21-22
0-1-4-7-9-12-13-15-19-21-22 ($E_{1,3}$)
0-1-4-7-9-12-13-14-16-20-22 ($E_{9,10}$,$E_{9,11}$)
0-1-4-7-9-12-13-14-16-20-22 ($E_{1,3} \cap E_{9,10}$,$E_{1,3} \cap E_{9,11}$)

It is found that DM(a) does not select a branch that becomes unavailable at the probability 0.65 but selects a branch that becomes unavailable at the probability 0.35. Note that unconditional occurrence probabilities are either 0.35 or 0.65 only. Moreover, if $E_{1,3}$ occurs, DM(a) selects a route without changes because all probabilities of changes increase to 0.8. This also shows that DM(a) selects the new optimal routes in response to real time information about the occurrence of changes.

DM(b) and (c) also select appropriate routes for their own subjective risk parameters τ and σ, that is DM(b) selects route in risk averting manor and DM(c) selects route paying less attention to the difference in objective probabilities as compared to DM(a), and DMs select better routes in response to real time information if changes of actions are caused on the way.

We do not treat conditional probabilities given three or more events as described in section 4.2. Simultaneous changes of three or more actions seldomly happen. Therefore, there are few chances that the agent selects actions when three or more events occur. In RL, because action values are updated only after taking those actions, the values of actions under the condition that three or more events occur do not converge. For this reason, we do not consider conditional probabilities given three or more events.

5 CONCLUSIONS

In this paper, we proposed RL approach to obtain the optimal policies in MSDM problems with changes of action sets considering DM's subjective views. It has been shown that the optimal policies are learned which correspond to DM's subjective views.

In contrast to standard RL methods that find the only one optimal policy, the proposed method can select routes in response to real time information during performing actions. This feature is promising in practical applications.

In future work, the issue must be solved that the conditional action values given three or more events do not converge. We have assumed that all probabilities are known, but it is desirable to estimate probabilities by learning.

Abstract: There are many researches about applying machine learning to robot. Robot uses sensors as input information for learning. When robot performs various task, sensors which are used for each task is important. The reason is important sensors for performing task are different in each task. Robot should use proper sensors for each task. Therefore, we will propose a method which robot can autonomously make a choice of important sensors for each task. We define measure of importance of sensor for task. The measure is coefficient of correlation between sensor value of each sensor and reward on reinforcement learning. Robot decide important sensors based on correlation. Robot reduce learning space based on important sensors. Robot can learn efficiently by reduced learning space.

Keywords: Reduction of learning space, Robotics, Data mining, Reinforcement learning

1 INTRODUCTION

In recent years, robots which have various sensors and actuators are appeared with development of hardware technology. These robots is hoped to use for various task. In order for robot to perform various task, there are many researches about applying machine learning to robot[1]-[3]. Learning for robot is to obtain correspondence between input and output for achieving purpose. The input is information from installed sensors and output is action of robot.

Robot uses sensors as input for learning. The way of use of sensors is important for task. When robot is used for various tasks, installed sensors which are used becomes a problem. The problem is that learning efficiency can be down depend on the way of use of installed sensors in some tasks. Because important sensors for performing task are different. Robot has important sensors and unimportant sensors for a given task. Input of robot is increase for unimportant sensors. When input is increase, the number of corresponding action which agent should learn to input increases. Therefore, learning time increases by using unimportant sensors for learning. As the result learning efficiency is down.

Therefore, robot should learn by using important sensors only for efficient learning. To achieve this, robot should have ability which robot makes a choice of important sensors for task. Our purpose is to propose a system which robot can make a choice of important sensors for any task and robot can learn efficiently by using information from important sensors only.

This system is effective to various task. Robot can make a choice of important sensor for changed task by this system. And information which robot should learn, which is correspondence between information from sensors and action is reduced. As the result, robot can learn efficiently.

2 CONCEPT OF MAKING A CHOICE OF IMPORTANT SENSORS

To make a choice of important sensor, robot needs measure of importance of each sensor for task. We focus on correlation sensor value and degree of achievement of task as the measure of importance of each sensor for task. Many tasks have correlation sensor value and degree of achievement of task. For example, in garbage collection task robot need to approach a garbage to pick up it. Degree of achievement of task is shown distance between the robot and the garbage, and increases as the robot approaches the garbage. There is a correlation between the degree of achievement of the task and distance between robot and the garbage like this.

We show outline on fig.1. Fig.1 shows the case which robot has 2 kinds of sensors, but robot can have more than 2 kinds of sensors. This robot has sensors and ability to act. The robot recognizes environment around the robot by installed sensors. Environment around the robot expressed group of sensor value of each sensor. The robot collects sensor value of each sensor and degree of achievement of task.

When robot act, sensor value of each sensor is changes. Therefore, robot can collect sensor value of each sensor by repeating action. Robot also collects degree of achievement of task. Robot estimates degree of achievement of task based on change of sensor value of each sensor. Environmental information which robot recognizes changes before and after action. Therefore, robot can know whether changed sensor value is good of not for performing task. In example of garbage collection task, focusing on distance sensor for garbage, when move for a garbage, the distance sensor value reduces. When the robot recognize the reduced distance sensor value, the robot can know current distance sensor value is good for performing the garbage collection task.

The robot finds out correlation between sensor value of each sensor and degrees of achievement of task. In fig.1, robot finds out correlation about sensor 1 and sensor 2. There are negative correlation and positive correlation. The robot estimates important sensors which has negative or positive correlation.

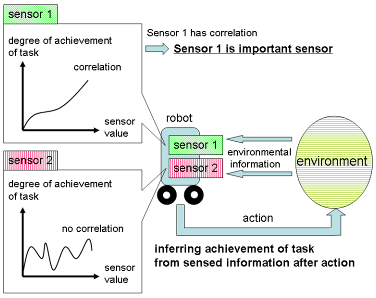

Fig. 1. The outline of making a choice of important sensors

3 PROPOSED SYSTEM ON REINFORCEMENT LEARNING

3.1 Outline of proposed system

The proposed method are used for efficient learning. Therefore, the proposed method is used in combination with a machine learning method. In this paper, we apply reinforcement learning as learning method(RL)[4]. The reason of applying RL is often adopted for experimental robots[5].

We show the system we propose in fig.2. In fig.2, the proposed system is divided into two part. One is the proposed method which robot makes a choice of important sensors. Another is reinforcement learning.

In the proposed method part, robot makes a choice of important sensor for task based on correlations between each sensor and degree of achievement of task. In RL, degree of achievement of task is shown as reward. Robot collects sensor value of each sensor and reward. Robot calculates correlation between each sensor and reward. Then robot decide important sensors based on correlation.

In reinforcement learning, robot learns proper action for task. In this part, there are action evaluation part, creating temporary Q-space based on important sensors part, and action selection part. Action evaluation part is updating evaluation for pair of state and action. State is composed of sensor value of each sensor. In creating temporary Q-space based on important sensors part, robot creates temporary Q-space which is composed of important sensor only. In action selection part, robot select action for recognized state by sensor based on temporary Q-space.

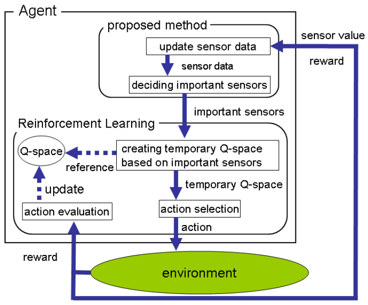

Fig. 2. The outline of proposed system

3.2 Decision of important sensors based on correlation

In proposed method, robot decides important sensors based on correlation between sensor value of each sensor and reward. Robot has sensor value of each sensor and reward which robot has experienced as knowledge. But reward is given for state-action pair. Therefore, there are some reward pattern for a state by an increment of the number of action. In this study, rewards for the state where robot experienced are averaged. Averaged reward at state s is r'_s.

Robot stores sensor value of each sensor and averaged reward as two lists in fig.3 and fig.4. There are state id and sensor value of each sensor in experienced states list. The state id is identification number. The list in fig.3 is an example of experienced states list. There are state id and averaged reward in averaged reward list. The list in fig.4 is an example of averaged reward list.

When robot recognizes state which is not in experienced states list, the robot adds the recognized state. Then robot calculates r'_s and added r'_s, to the averaged reward list. When recognized state is in the experienced states list, robot calculates r'_s and updates r'_s at recognized state in the averaged reward list.

state id	sensor value of sensor 1	sensor value of sensor 2	• • •	sensor value of sensor n
1	s	56	• • •	111
2	23	45	• • •	123
⋮				
m	90	10	• • •	15

Fig. 3. The experienced states list

state id	r'_s
1	111
2	123
⋮	
m	15

Fig. 4. The averaged reward list

Robot calculates coefficient of correlation based on the experienced states list and the averaged reward list. C_j as coefficient of correlation of sensor j and r'_i is calculated by eq.(1).

$$C_j = \frac{\sum_{j=1}^{m}(s_{i,j} - \bar{s}_i)(r'_{,i} - \bar{r'}_i)}{\sqrt{\sum_{j=1}^{m}(s_{i,j} - \bar{s}_i)^2}\sqrt{\sum_{j=1}^{m}(r_{j-\bar{r'}})^2}} \quad (1)$$

The i is identifying number of sensor. The $s_{i,j}$ is sensor value at state id i and sensor id j at the experienced states list. The r_j is averaged reward at state id j in the averaged reward list. The C_i is calculated for each sensor every action. Robot decides important sensor by comparing $|C_i|$ and Th. The Th is threshold to judge important sensor. When the $|C_i|$ is over Th, robot judges sensor as important sensor.

3.3 The way of use of important sensor for learning

Important sensors are used for selection of action in reinforcement learning. Creating temporary Q-space which is composed only important sensor axes by reduction for unimportant sensor axes. Reduction for Q-space is learning space. Reduction for Q-space is to project Q-values in unimportant sensor axes to Q-values in important sensor axes. Fig.5 shows an example of degeneration of Q-space. Important sensor is S_1, unimportant sensor is S_2 in this example. Q-values in S_2 is projected to Q-values in S_1. Projection is addition Q-values in S_2 to Q-values in S_1.

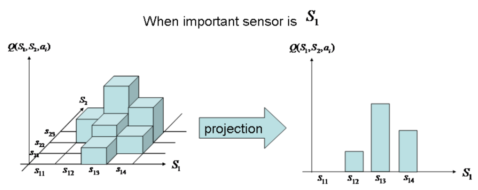

Fig. 5. The projection for temporary Q-space

We formulate based on this outline. Q-value is averaged reward by the number of experience of state-action pair. The number of experience for each state-action pair can be difference. This difference means difference of confidence of Q-value for state-action pair. Therefore, we consider weighted averaging Q-value according to the number of experience. To do this, we estimate total reward based on Q-value and the number of experience for state-action pair. Temporary Q-space is created based on total reward and the number of experience for state-action pair.

Temporary Q-space is used for selection of action at current state. Therefore, we consider projection at only current state of robot. Current state of robot is shown as $S = e_{1,f}, e_{2,g} \ldots, e_{n,z}$. The $e_{1,f}$ means f th sensor value in sensor 1. States of important sensors are shown as $S^{\star} = e_{1,f}, e_{2,g} \cdot \ldots \cdot e_{p,k}$. States of unimportant sensors are shown as $U = e_{p+1,x}, e_{p+2,y} \ldots e_{n,z}$. Total reward of any action at state S ($R(S,a)$) is defined as eq.(2).

$$R(S,a) = R(S^{\star}, U, a) = Q(S,a) \times E(S,a) \qquad (2)$$

The temporary Q-value $Q(S^{\star}, a)$ is defined as eq.(3). The $E(C,U,a)$ is the number of experience of state action pair $(S^{\star}, U, a)$.

$$Q(S^{\star}, a) = \frac{\sum_x \sum_y \cdots \sum_z R_{total}(C,U,a)}{\sum_x \sum_y \cdots \sum_z E(C,U,a)} \qquad (3)$$

We apply ϵ-greedy method for selecting action. The ϵ-greedy method selects the action which has the highest Q-value basically in current state S. But the method selects an action randomly with probability ϵ.

3.4 The action evaluation

We apply weighted averaging method as action evaluation method. The weighted averaging method evaluates by giving weight to reward which robot obtains recently. When current state of robot is S and the selected action is a, Q-value($Q(S,a)$) is updated by eq.(4). The $\alpha$is step size parameter ($0 \leq \alpha \leq 1$).

$$Q(S,a) \leftarrow Q(S,a) + \alpha \left[r - Q(S,a) \right] \qquad (4)$$

4 EXPERIMENT TO CONFIRM EFFECTIVENESS OF THE PROPOSED SYSTEM

4.1 Outline of experiment

In this section, we examine effectiveness of the proposed system on computer simulation. Environment for the experiment is shown fig.6. This environment is grid field u $\times$ u which is surrounded by walls. Length of both walls is u squares. We prepare virtual robot which is called agent. Agent has two distance sensors. One can measure distance between current position of agent and wall A in fig.6. Another can measure distance between current position of agent and wall B. Agent can move up, down, right and left.

In this experiment, agent performs two kinds of task. One is to depart from wall A. Another is to depart from wall A and wall B. Agent can obtain reward according to distance from wall A or both walls. Agent is allocated upper left of environment. When agent move n_{act} times, task is finished.

We confirm effectiveness of the proposed system by comparing the proposed system and ordinary RL. Therefore we prepare two types of agents to compare. One is applied the proposed method. Another is applied the RL only. In the case of the RL only, robot uses all installed sensors. We compare these agents in obtained total reward after moving n_{act} times.

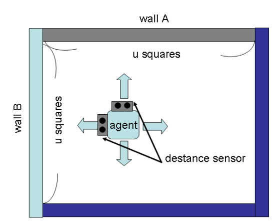

Fig. 6. The environment for the experiment

4.2 The setting of this experiment

We explain about reward for each task and show parameter settings. First, we explain about reward for each task.

In task A, agent can obtain higher reward with increasing the distance between current position of agent and wall A(d_A). Reward of task A is defined in eq.(5).

$$r = d_A \tag{5}$$

In task B, agent can obtain reward based on d_A and the distance between current position of agent and wall B (d_B). Agent can obtain higher reward with increasing both d_A and d_B. Reward of task B is defined in eq.(6)

$$r = d_A + d_B \tag{6}$$

We show parameter settings of this experiment at table.1.

Table 1. The settings of experiment

u	20
n_{act}	20000
ϵ	0.1
α	0.7
initial value of Q-value	0
Th	0.6

4.3 Result and consideration of the experiment

We show result of experiment fig.7 and fig.8. First, we discuss the result about task A. Fig.7 shows obtained reward of agent at each action. The proposed method shows higher convergent of reward than reinforcement learning under 5000 actions. The reason is that robot could select proper sensor for learning by the proposed method. Temporary Q-space has more information than Q-space because of projection of Q-space. The agent using temporary Q-space was easy to select proper action for recognized state.

Next, we discuss the result about task B. Fig.8 shows obtained reward of agent at each action. The proposed method was unstable in early phase of learning(under 5000 actions). The reason is that agent which was applied the proposed method spent times to estimate important sensor. Reward in task B is depend on d_A and d_B. Agent need to collect more sensor and reward data than the case of task A. In early phase of learning, agent selected unimportant sensor because of a lack of sensor and reward data. Therefore reward of agent which was applied the proposed method was lower than agent which was applied reinforcement learning only.

From these result, the proposed method is effective in the case of task which agent uses a part of installed sensor of agent. In the case of task which agent uses all installed sensors of agent, performance of learning in the case of the proposed method is lower than in the case of use of all installed sensors. But agent which is applied the proposed system can change sensors according to importance of each sensor to a task. The agent can learn faster depending on task.

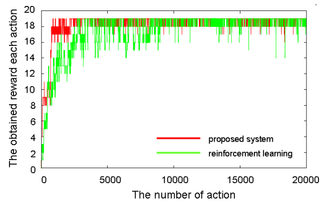

Fig. 7. Obtained reward at each action in task A

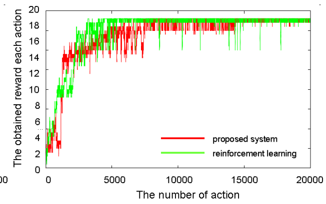

Fig. 8. Obtained reward at each action in task A

5 CONCLUSION

In this paper, we proposed the method which robot makes a choice of important sensors for a task. We constructed a system which is composed proposed method and reinforcement learning. This system is that robot can learn efficiently by the proposed method. We examined effectiveness of the constructed system on simulation. From result of simulation, we confirmed effectiveness of the constructed system and the proposed method. We confirmed robot can learn efficiently by making a choice of important sensors. We will attempt to install this proposed system into actual robot and examine effectiveness as our future work.

Abstract: Synchronicity observed in a group of fireflies was reconstructed using SunSPOTs. It is based on the software simulation with phase delay model. The main purpose is to provide a method for performing synchronicity among electronic fireflies, rather than obtaining clock synchronization. Some problems arising from the use of real wireless devices, not occurred in the simulation, were addressed and solved. The most important problem was how to send and receive phase delay information among SunSPOTs using real ratio signal. This is not the problem in the simulation because the detection of other flashes can be immediately obtained by simple calculations. The results from the proposed implementation exhibit relatively good synchronicity although its accuracy is not so high. These can be useful to observe synchronous behavior in the biological population without leaders.

Keywords: network synchronicity, sensor network, synchronization

1 INTRODUCTION

Many applications using wireless sensor network technology require time synchronization among each local clock on the devices connected to the network. But it is hard to get an efficient method for it. On the other hand, *synchronicity* is not the same as *time synchronization,* and the both are complementary each other. Synchronicity is considered as the ability to organize simultaneous collective action across a network (Werner-Allen et al [1]). Many research papers on synchronicity inspired by fireflies have been published (Werner-Allen [1], Tyrrell [2], Leidenfrost [3]). However, most of them except Werner-Allen [1] take software simulation, where uncertain behavior and delay in communication are not considered.

In this paper, an implementation method for synchronicity that does not use a centralized signal is presented, and demonstrated on a realistic experimental radio network. This method is based on the synchronicity that has been observed in nature in large populations of fireflies. My paper does not ask for very accurate synchronous behavior because the objective is to demonstrate fireflies' synchronicity on electronic devices. The accuracy of about several milliseconds is good enough to observe flashing of fireflies by human eyes. I proposed a method for synchronicity, and implemented it on the devices as shown below. In the following, at first, flashing behavior of fireflies without leaders is analyzed by a simulation using NetLogo (Wilensky [4], Wilensky [5]). Next, my implementation on a group of SunSPOTs (Smith [6], Simon [7]) is presented. Finally some experimental results are presented.

2 ANALYSIS OF FIREFLY SYNCHRONICITY USING NETLOGO

In the NetLogo's model library, there is an application to simulate behavior of populations of fireflies. It exhibits simultaneous flashing of all the fireflies without leader. I made concise version of it to investigate the mechanism of such synchronous actions. The interface window is illustrated in Fig. 2.1. Some related parameters are set as follows:

[number of fireflies]= 4
[cycle-length] = 6 time ticks
[flash-length] = 2 time ticks
[flashed-to-rest] = 1

Four fireflies are deployed horizontally to one line. They are identified as Firefly-0 (#0), .., Firefly-3 (#3). The distance between adjacent fireflies is set to one (1). This numbering of fireflies is made in round-robin manner, so that the distance between #0 and #3 becomes one. Each firefly tries to adjust its flashing phase to the neighboring one that other emission. It is assumed here that one can receive the emission within the distance 1. The firefly that receives such emission reset its time tick to the value of the flash-length. This resetting occurs only after the flashing and never occurs during its own flashing. Therefore, this makes the receiving firefly delay the phase after its flashing.

Detailed procedures in NetLogo are shown in Fig. 2.2.

Fig. 2.2 Procedures in the NetLogo simulation

The results obtained by executing these procedures are illustrated in Fig. 2.3. At the starting point (time tick = 0), four fireflies are in different phase. Only #1 is in flashing interval. The #0 immediately detects the flash from #1 and resets its phase to the value of the flash-length. The same action occurs in the #2. When time tick advances to one, the #1 is still in flashing mode. Therefore, phase delay occurs again in both #0 and #2. When time tick advances to two, the #1 completes its flashing, but the #3 is still in flashing mode. In this situation, both #0 and #2 detects flashing from the #3. This causes the #0 and #2 again reset their phase to the value of flash-length. After that, others affect no fireflies for a while.

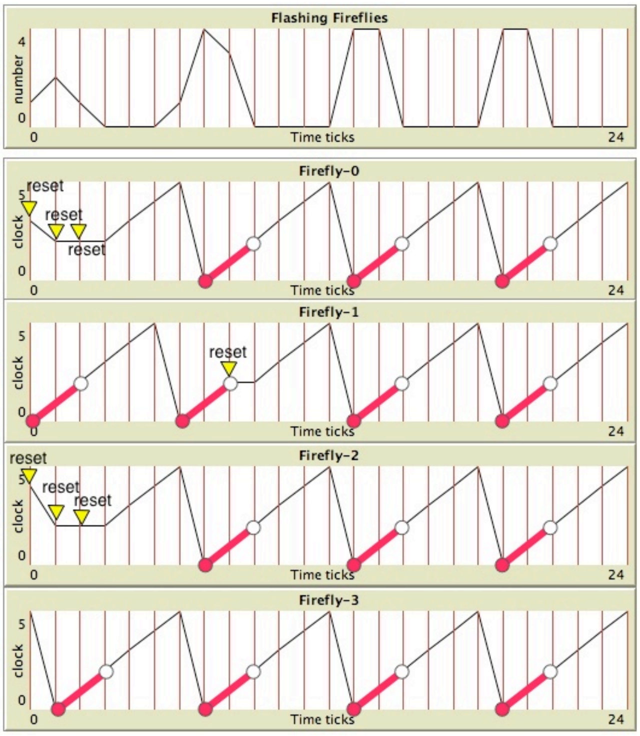

Fig. 2.3 The analysis of the phase delay model

The next notable point is the time when time tick becomes eight. At this point, the #1 detects flashing from either #0 or #2. Therefore, when time tick advances to nine, the #1 resets its phase to the value of flash-length. After the time tick becomes thirteen, all the fireflies exhibit synchronous behavior, and this synchronicity will be continued forever.

3 IMPLEMENTATION OF SYNCHRONICITY ON SUNSPOT

Flashing of fireflies was implemented on a group of small devices with wireless communications. The proposed method for it is based on the NetLogo simulation mentioned above. That is, the phase delay mechanism affecting to the flash cycle, is adopted. However, there are some important issues, which were not appeared in the simulation. They are discussed below.

3.1 Issues in implementation on SunSPOT

The present implementation of the proposed method has been performed on a set of tiny Java machine SunSPOTs Smith [10], Simon [11], Akriboulos [12]. One SunSPOT corresponds to one firefly as illustrated in Fig. 3.1. Each SunSPOT has ZigBee-based radio communication facilities, which exchange clock delay information.

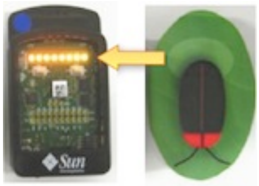

Fig. 3.1 Electronic firefly using SunSPOT

In NetLog simulation the problem of how to detect the flashes of other fireflies does not occur because other nearby flashes are obtained immediately by a simple calculation based on positional information. On the other hand, with SunSPOT, the flash is expressed and emitted by a radio signal, so that other SunSPOTs should be able to receive the flash. Since flashing occurs erratically throughout the population, each SunSPOT generates multiple threads on which other flashes starting at different times can be received.

Another problem is that no global clock exits in the implementation on SunSPOTs differently in the case of NetLogo simulation. In the simulation explained above, all the fireflies refer to one global clock, even though they are in different phases. Namely, as shown in Fig.2.3, all fireflies act based on the common time ticks. Therefore, delay value to synchronize with others always becomes an integer multiples of one time tick. This is not true on SunSPOTs because fireflies must calculate the difference between the starting time of its own flash and the receiving time of other flash by their own local clock. This difference does not necessarily become an integer multiples of one time tick. This implies that synchronicity and time-synchronization are not the same, as shown in the introduction.

3.2 Principles of the implementation

Each firefly on a SunSPOT counts up time ticks in its own clock during the cycle-length. When it reaches the max (i.e. cycle-length), the count is reset to zero. When a firefly becomes time tick zero, it begins flashing and continues it during the flash-length, in which other flashes do not affect the firefly although it can receive other flash. Flashing is realized by broadcasting a packet that has special header. Once the firefly detects other flashes, then it does not receive other flashes for a time. When the firefly receives other flashes, the firefly can calculate the necessary delay time. The delay is the difference between the receiving time of other flash and the starting time of its own flash. The delay is added at the end of the current flash cycle. It is expected that the firefly synchronizes its own flashing at the next cycle with that of the firefly sending the packet.

However, in the real world, several problems can be observed. For example, some pairs of SunSPOTs may maintain fixed value of delay each other for a long time, depending on the startup timing, as shown in the next section. Also, cycle time of each SunSPOT may gradually become disordered. Due to this, synchronicity that is observed may lose accuracy even though essential framework of synchronicity is preserved. In order to settle these problems, it is necessary for a SunSPOT that has been received other flash can get again another flashing signal after several cycles. Such correction seems unavoidable when using many devices with limited timing accuracy.

4 RESULTS AND ANALYSIS

Experiment of this implementation using four to eight SunSPOTs has been performed. The radio output power was set to the minimum so that broadcast range is limited within 20 cm. All the SunSPOTs are aligned into a line. The distance between two SunSPOTs is set to 15 cm. Therefore, each SunSPOT can receive broadcast message only from the neighbors. In this situation, each SunSPOT is started in different time, and human eyes observed the process to the synchronicity. For the group of four SunSPOTs, synchronicity was obtained after two to four cycles. For the group of eight SunSPOTs, it took more cycles but less than six cycles until steady state of synchronicity. Occasionally, disorder of synchronicity was observed. However, the synchronicity was recovered approximately after four to six cycles. Typical two cases observed in the experiment are analyzed in Fig 3.2 and Fig 3.3.

Fig.3.2 shows the group of four SunSPOTs, in which each SunSPOT begins its flashing at random time point. The #1 detects flashing of #2 during its own flashing interval. The delay d1 (difference between the start time of #1 and the start time of #2) was added at the end of the current cycle of #1. This causes synchronicity between #1 and #2 at the next cycle. On the other hand, the #4 detects the second flashing of #3 outside of its flashing interval. The delay d3 (the delay against #3) was added at the end of normal cycle of #4. Any other SunSPOT never disturbed the #2. After two cycles of #1, all four SunSPOTs agreed to synchronize.

Fig.3.3 illustrates different behavior compared to Fig3.2. Note that the cycle-length is changed against the case of Fig. 3.2. to make it easy to explain. One time tick regularly shifts the starting time of three SunSPOTs. The #2 was delayed for d2 (against #1) because #2 detects flashing from #1. By this, the #2 agreed to synchronize with #1. In the same way, #3 tried to synchronize with #2 by adding the delay d1 (against #2) at the end of its cycle. But the #2 and the #3 did not synchronize each other, because the #2 was already delayed for d2. No synchronicity seems to be obtained after that. But at this point, the flag for permission of getting other flash was set as on. (How often this permission is set is indicated as an optional parameter.) Then, reversely, #2 detects the flash from #3, and #1 detect the flash from #2. As a result, all three SunSPOTs went into synchronicity after several time ticks.

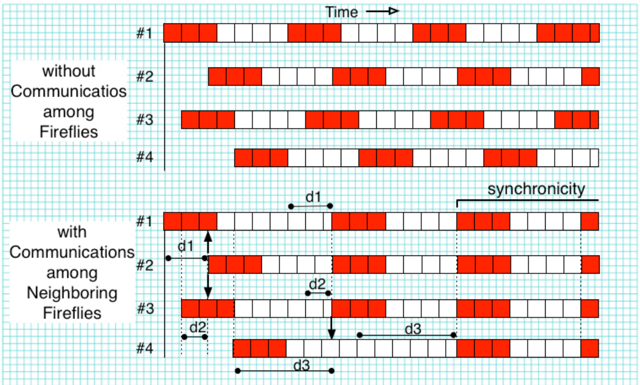

Fig. 3.2 Analysis of randomly started fireflies

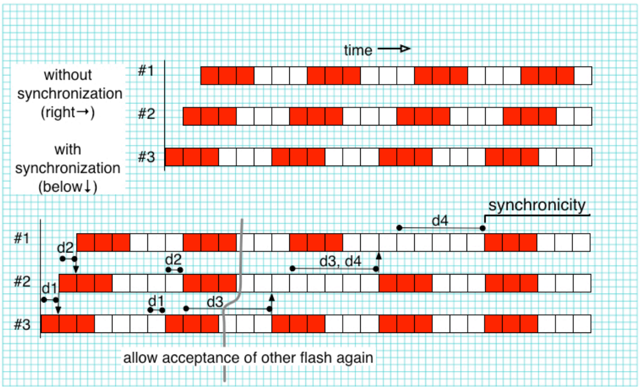

Fig. 3.3 Analysis of regularly started fireflies

5 CONCLUSION

Synchronicity observed in a group of fireflies was reconstructed using four to eight SunSPOTs. It is based on the software simulation with phase delay model. Some problems arising from the use of real wireless devices, not occurred in the simulation, were discussed and solved. The most important problem was how to communicate between SunSPOTs using real ratio signal. This is not the problem in the simulation because the detection of other flashes is immediately obtained by simple calculations. The results from the proposed implementation exhibit relatively good synchronicity although its accuracy is not so high. These can be useful to observe synchronous behavior in the biological population without leaders. Also, it is meaningful to demonstrate the proposed implementation in the education of embedded software development.

Abstract: We describe an approach for cooperative multi-robot localization based on Monte Carlo Localization. In our approach, each of the robots maintains its own clustering based MCL algorithm, and communicates with each other whenever it detects another robot. We develop a new information exchange mechanism, which makes use of the information extracted from the clustering component, to synchronize the beliefs of detected robots. By avoiding unnecessary information exchange whenever detection occurs through belief comparison, the proposed approach solves the delayed integration problem which further improves the effectiveness and efficiency of multi-robot localization. This approach has been tested in both real and simulated environments. Compared with single robot localization, the experimental results demonstrate that proposed approach notably improves the performance, especially when the environments are highly symmetric.

Keywords: clustering, MCL, multi-robot localization

I. INTRODUCTION

Mobile robot localization, the process of determining the position and orientation (pose) of a robot within its operating environment from sensor reading, is a prerequisite for subsequent high level navigation tasks. It has been considered as one of the fundamental problems in mobile robotics [6]. The most widely studied localization problems are: Local localization (position tracking), which is to compensate incremental errors in a robot's motion under the assumption that the initial position is known as prior, and the more challenge Global localization, in which the robots are required to estimate their pose by local and incomplete observed information under the condition of uncertain initial position [7].

During the past two decades, most existing work has focused on single robot localization, such as Grid-based approaches [1], Monte Carlo Localization [5, 11], and multi-hypothesis approaches [2]. These approaches have been applied to many different applications in solving localization problem and achieve remarkable successes.

However, more and more researchers are interested in using multiple robots to improve efficiency and robustness. In this paper, we propose an efficient probabilistic approach for cooperative multi-robot localization in indoor environment. Our approach is based on Monte Carlo Localization that has been applied with great practical success to single robot localization. In our approach, the robots, capable of sensing and exchanging information one with another, localize themselves by maintaining their own beliefs which are the proposed clustering based MCL algorithm. Our new developed information exchange mechanism is employed to synchronize each robot's belief whenever one robot detects another in order to speed up the localization process with possible higher accuracy. We utilize the information extracted from the clustering component of the proposed approach which analyzes the distribution of the whole particle set to quantify robot's belief and transfers information across different robots if necessary. We always compare the beliefs of both detected robots before synchronizing their poses' estimate to control information integration. By doing so, we can prevent the localization process from suffering the problem of delayed integration, which means to avoid unnecessary information exchange. In addition, robots themselves are implicitly used as landmarks rather than using only external landmarks, as in other works.

In section II we briefly review previous cooperative localization approaches, the MCL algorithm, and the clustering method. Section III describes details of our proposed method. Section IV presents the experimental results. Finally, section V provides the conclusions and future work.

II. RELATED WORKS

Many robotic applications require that robots work cooperatively in order to perform a certain task [9]. Knowing their global positions is the first step in multi-robot systems.

One early cooperative localization technique with multiple robots was proposed by Kurazume and Nagate [8] ans is known as "portable beacons". The basic underlying idea is that each robot repeats move-and-stop actions and serves as a landmark for the other robots. Only a part of entire robots can move in a certain time instant and this dramatically slows down the overall localization speed.

An EKF-based approach for cooperative multi-robot localization was introduced by Roumeliotis [11]. This approach allows all robots in a group to move simultaneously, and to propagate their state and covariance estimates independently by decomposing the centralized EKF-based cooperative localization into N communicating filters. However, during each update cycle, all robots need to communicate with each other and update the covariance matrix for all pose estimates. The main drawback is that the high cost of computation and communication limits this approach to small robot teams in real-time operation.

Fox and Burgard [4] have proposed a different implementation of cooperative multi-robot localization schema which extends the Monte Carlo Localization (MCL) algorithm. The sample-based version of Markov localization enables localizing mobile robots in any-time fashion. Each robot in the system maintains a probability distribution describing its own pose estimate. When one robot detects another, the "detection model" is used to synchronize the individual robot's beliefs, thereby introducing additional probabilistic constrains which ties one robot's belief to another robot's belief to reduce the uncertainty. This method suffers from the problem of delayed information exchange, which means the information exchange between two detected robots cannot ensure it is always benefit the localization process.

Our proposed approach is a clustering based MCL algorithm for cooperative multi-robot localization. The details of MCL and the related clustering algorithm will be given in this section. We first review some basic concepts in mobile robot localization. The *state* of a robot is defined as the collection of all aspects of the robot and its environment. The state at time t is denote as x_t. The pose of a robot is denoted (x, y, θ), where x and y represent a two-dimensional coordinate and θ represents orientation of the robot. The notion of *belief* is used to represent the robot's internal knowledge about the state of the environment [10]. The expression of belief over state x_t is $bel(x_t) = p(x_t|z_{1:t}, u_{1:t})$. It is a posterior probability over states conditioned on all the past motion data $u_{1:t}$ and all the past measurement data $z_{1:t}$. Localization algorithms based on probabilistic methods have two different components to process these two kinds of data [13]: measurement model, denoted as $p(z_t|x_t)$, and motion model, denoted as $p(x_t|u_t, x_{t-1})$.

A. Monte Carlo Localization

Monte Carlo Localization (MCL) is one of the latest and commonly used probabilistic approaches for single robot localization. MCL is an implementation of Bayes Filter, which represents uncertainty by maintaining a set of weighted samples that are randomly drawn from the probability density [19].

MCL is a recursive algorithm, and Fig. 1 [19] shows one iteration. The inputs of the MCL algorithm are particle set X_{t-1} from previous iteration, control data u_t, measurement data z_t, and the given map m of the environment. Line 1 initializes the particle set $\bar{X}_t$ and X_t. And then for each particle, line 3 do sampling from the motion model, line 4 calculates the importance weight of that particle from the measurement model. Line 7 to line 10 is the resampling phase. The algorithm draws with replacement N particles from the temporary set $\bar{X}_t$. The probability of drawing each particle is given by its importance weight. Finally, the posterior particle set X_t, which contains the particles that with higher importance weights is returned.

Algorithm MCL ($\boldsymbol{X_{t-1}, u_t, z_t, m}$)
1: $\bar{X}_t = X_t = \emptyset$
2: for n =1 to N do
3: $X_t^{[n]}$ = sample_motion_model (u_t, $X_{t-1}^{[n]}$)
4: $w_t^{[n]}$ = measurement_model (z_t, $X_t^{[n]}$, n)
5: $\bar{X}_t = \bar{X}_t + < X_t^{[n]}, w_t^{[n]} >$
6: endfor
7: for n = 1 to N do
8: draw i with probability $\propto w_t^{[i]}$
9: add $x_t^{[i]}$ to X_t
10: endfor
11: Return X_t

Fig. 1. The Monte Carlo Localization (MCL) algorithm [19].

Note that, if MCL finishes successfully, most particles are concentrated on a small region which represents the location of robot, although there is not such a stop condition in the MCL algorithm.

B. Clustering Algorithm BSAS

Clustering is the assignment of a set of observations (particles) into clusters so that observations in the same cluster are similar to each other. Two important parts in almost all clustering algorithms are to select a proximity measure, which measures the dissimilarity between particles or clusters, and the representative of a cluster, which highly depends on the shape of a cluster. As in MCL all poses of particles are represented by a two dimensional coordinate system, it's more effective for us to choose the Euclidean distance measure $d(P_i, P_j) = \sum \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}$ as our proximity measure. A Compact cluster is what one mostly encounters in MCL, thus the mean point of a cluster is chosen as representative, denoted as $P_{mean} = \frac{1}{N} \sum P_i$, N is the number of particles contained in that cluster.

We choose one of the most efficient clustering methods called Basic Sequential Algorithm Scheme (BSAS) shown in Fig. 2. to be used in the proposed method, because most probabilistic robotics algorithms need real time performance.

The BSAS algorithm takes the whole particle set $X(x_i, \dots x_N)$ that need to be clustered and the user defined threshold of dissimilarity θ as inputs. Line 1 initialize the first cluster, which contains the first particle x_1 presented to the algorithm. From line 2 to line 9 it is a large for loop sequentially going through all the remaining particles. The dissimilarity measures between current particle and every existing cluster is calculated in order to find a minimum one in line 3. From line 4 to line 8, if the minimum measure calculated in line 3 is greater than θ, a new cluster that containing current particle will be created. Otherwise, the considered particle will be assigned to the existing cluster which has the minimum dissimilarity measure to it and update its representative of this cluster.

Algorithm BSAS ($\boldsymbol{X(x_i, \ldots x_N), \theta}$):
1: $m = 1, C_m = \{x_1\}$
2: for *i =2 to N* do
3: find $C_K: d(x_i, C_k) = min_{1\leq j \leq m} d(x_i, C_j)$
4: if $d(x_i, C_k) > \theta$ then
5: $m = m + 1,\ C_m = \{x_i\}$
6: else
7: $C_k \cup \{x_i\}$, update its representative
8: endif
9: endfor

Fig. 2. The Basic Sequential Algorithm Scheme (BSAS) [12].

III. COOPERATIVE CLUSTERING BASED MCL ALGORITHM

Motivated by both the MCL and the BSAS algorithms above, one novel method incorporating clustering into the conventional MCL is proposed for cooperative multi-robot localization in order to further improve the localization performance, as outlined in Fig. 3.

A. MCL+BSAS part

Our proposed approach consists of three parts. In the first part, each robot maintains its own belief by executing the MCL and the BSAS algorithms. The conventional MCL is used and the generated particle set is then supplied to the BSAS algorithm for clustering (the clustering component). By doing so, the proposed approach could monitor the localization process of each robot in real time by making use of the cluster information obtained from BSAS, such as the number of clusters, denoted as n_c, the locations of these clusters, denoted as $pose(a_1, \cdots, a_n)$, the possibility of each cluster represent the true location of the robot. If the percentage p_{max} of particles in the cluster which contains the largest number of particles exceeds a predefined threshold η, then the considered robot is assumed to have been localized, and return the pose of representative of the cluster to be used as a landmark for the other robots. If p_{max} is less than the predefined threshold η, then it indicates the robot fails to localize itself at the moment. The ability that recognizing whether a robot has been l localized or not by itself significantly improves its robustness and autonomy.

B. Detection part

The core idea of multi-robot localization is to let the robot benefit from information collected by others, therefore the interactions between robots is essential to the proposed approach. Robot can perceive other robots in the environment, and then exchange their information with each other if possible to reduce their uncertainty about their external environment. In part 2, the proposed approach manages the behavior of both detected robots in a principled way in order to dealing with the delayed information exchange problem.

Algorithm: Clustering based MCL for multi-robot localizatoin

Part 1:

Initially, each robot executes its own MCL+BSAS to monitor its own pose estimate and cluster information.

If the degree of certainty p_{max} exceeds a predefined threshold η, the considering robot will stop to indicate it has been localized and return its location to be used as landmark for other robots.

Part 2:

When one robot detects another:

(a) If the values of both detected robots' status variables are false, there is no information exchange;

(b) Else there is one robot's status variable is true or both of them are true, then do belief comparison:
  If they are not with the same degree of certainty, do information exchange which use the one with higher certainty to help the other one to refine its pose estimate;
  Else there is no information exchange;

Part 3:

Process of information exchange:

(a) After determining the exchange direction, a predefined distance threshold γ is used to help in refining process:
  Those clusters of the robot with lower certainty, whoever is within the range of predefined distance threshold γ to any clusters of the robot with higher certainty, will be kept;

(b) Return a new set of clusters which will focus on the more possible locations of the robot;

(c) Uniformly resample *N* total particles within the newly returned set of clusters;

Fig. 3. The Clustering based MCL for cooperative multi-robot localization

The behavior is mainly to determine whether to allow an information exchange and the direction of information exchange, with the help of one important Boolean type status variable for each robot described in Fig. 4. Initially, each status variable is set to be "False". During the entire localization process, once a robot has detected any landmark, its status variable will be set to "True", and once a robot has exchanged its belief with another robot, the status variable will be set to "False". If one robot has succeeded in its localization, its Boolean value will always stay in "True"

We manage the detection between robots in two scenarios: (1) in the first scenario, both status variables of two detected robots are false. This scenario includes two situations: (a) both robots have not detected any landmarks yet. Here we can assume that the internal beliefs of both robots about their poses relative to the environment are very blurry.

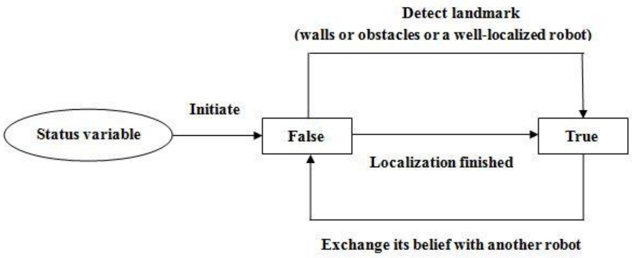

Fig. 4. The status variable diagram.

We skip the information exchanging at the moment since the blurry knowledge will not benefit the localization process. (b) Both robots have already exchanged their beliefs at last encounter or detection, and no landmarks have been observed by both robots yet at current detection. Without a newly observation of landmarks the level of uncertainty will most likely stay the same level or even worse. Normally there is no need to exchange information again. Therefore our approach does not allow the information exchanging under this kind of situations. (2) In the second scenario, there is at least one status variable value is true or both are true. Since perceiving a landmark helps robot gather more information about its environment so it could help in its pose estimate, we consider it as necessary to exchange their beliefs to refine the pose estimates. The direction of refining belief is to use the robot's belief which is with higher certainty about where it is to refine the other with lower centainty about its pose and hence it requires a comparison of the level of certainties about their locations. In order to quantify the belief, our approach makes use of the variable p_{max} extracted from the clustering component. Through comparing of p_{max} of both robots we can find which one is with higher certainty about its position. If they are with the same level of certainty, then we consider it as no need to exchange their information, however, this situation rarely happened in experiments.

Through this strategy our approach makes sure that the information exchange always benefits the localization process.

C. Information exchange part

As mentioned above, each particle or cluster represents one possible position of robot. If two robots detect each other, their estimated poses which are particles or the representatives of clusters should be within a certain distance. Our proposed approach makes use of this geometric relationship to build a mechanism for information exchange. Fig. 5 shows the pseudo code of the process of information exchange. It takes both sets of clusters of robot A and B, and the predefined threshold distance γ as inputs. The direction of information exchange has been determined by part 2, thus, we have two cases: (1) robot A refines robot B from line 1 to 10; (2) vice versa robot B refines robot A. In case 1, line 2 initializes a new set of cluster C'_B. From line 3 to line 8, it is a for loop going through all clusters of robot B. Line 4 calculates the distance between the current cluster of robot B and all clusters of robot A to find the minimum one, if the minimum distance is smaller than the threshold γ, then add it to the set of cluster C'_B. Line 10 uniformly resamples the total number of particles within the newly returned set of clusterC'_B. The process of case 2 is the same as case 1 but with different direction of information exchange.

Information exchange
($C_A(a_1, \cdots, a_m), C_B(b_1, \cdots, b_n), \gamma$):

1: *Case 1: Robot A refines Robot B*
2: $C'_B = \emptyset$
3: for *i =1* to *n* do

IV. EXPERIMENTAL RESULT

Our approach is tested on both real and simulated robots. In both situations, we firstly test the performance of single mobile robot localization, and then apply our approach to multi-robot localization. Three important data: the localization time $t(s)$, the successful rate ε, and the error distance d, will be collected in every experiment. Finally we compare these characteristic results of multi-robot localization with single robot localization, and demonstrate improvement.

A. Experiments Using Real Robots

Fig. 6. Two iRobot Create using in our experiments. The left Create is with black label, while the right one is regular Create.

Fig. 6 shows the two real robots iRobot Create using in our experiments. The experiments are conducted in four different environments shown in Fig. 7. The two Creates started from different locations. The paths of both Create is set to turn left 120° when it bumps to the wall or obstacle, otherwise keep going forward. The total number of particles used to represent the belief of Create is set to 5000. The dissimilarity measure threshold θ is set to 17cm which is the radius of Create. Therefore the shape of each cluster will be the same size as Create. The threshold γ used in the process of information exchange is set to be 60cm since the setup of detection is determined by the range of infrared signals emitted by Virtual wall sensor. Threshold η is set to 70%, which means if the number of particles contained in the largest cluster is equal or larger than 70% of total, the Create will stop to indicate it has been localized. We repeat each experiment 50 times and compare the performance to MCL+BSAS for single robot which ignores robot detections.

(c)
(d)

Fig. 7. Four environments of real robot experiments. (a) A rectangle field with the shape of 300cm×150cm; (b) Two rectangle fields, the left one is 150cm×150cm, the right one is 150cm×100cm; (c) A rectangle field of 300cm×150cm, and an obstacle of 31.5cm×19.5cm placed in the field; (d) Two rectangle fields, the left one is 150cm×150cm, the right one is 150cm×100cm, and an obstacle of 31.5cm×19.5cm placed in the field.

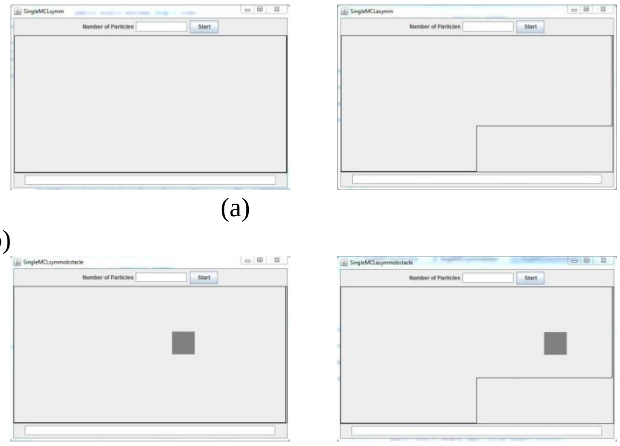
TABLE I.
COMPARE MULTI-ROBOT LOCALIZATION WITH SINGLE ROBOT LOCALIZATION USING CREATE

Environment		***t*** **(s)**	**Time saving (%)**	***ε***	**Increasing of successful rate (%)**
Symmetric	**Single robot**	230.88	37.6%	42%	30%
	Multi robot	144.04		72%	
Asymmetric	**Single robot**	81.6	25.6%	84%	2%
	Multi robot	60.73		86%	
Symmetric with obstacle	**Single robot**	92.62	24.9%	80%	4%
	Multi robot	69.54		84%	
Asymmetric with obstacle	**Single robot**	74.38	30.4%	90%	1%
	Multi robot	51.76		91%	

The results shown in Table I demonstrate that compare to single robot localization, our proposed approach applied in multi-robot localization not only reduces the time for localization, but also increase the successful rate for each robot. We can see without the help of detection of other Create and exchange information between them the time for single robot localization in symmetric environment is 230.88s, and the successful rate is only 42%. With the help of another Create, the results show significant improvement, which reduce the time for localization by 37.6% to 144.04s in average of two Create, and increase the successful rate by 30% to 72%. The large improvement of time saving also shows in the other three environments. However our proposed approach can only increase the successful rates by relatively small ranges in the other three environments. This is because these three environments are very distinctive which means even single Create can achieve high successful rate.

B. Simulation Experiments

The simulation experiments are also implemented in four different environments shown in Fig. 8. Same as in the real robots experiments, both multi-robot localization using our proposed approach and single robot localization have been tested under these four environments. The total number of particles is also 5000. The threshold γ is set to 120 pixels which is the same setup of detection with experiments using Create. The dissimilarity threshold θ is set to be 60 pixels, and threshold η is also set to 70%. We repeat each experiment 50 times.



(a)
(b)
(c)
(d)

Fig. 8. Four environments of simulation experiments. (a) A rectangle field of 600×300pixel; (b) Two rectangle fields, the left one is 300×300pixel, the right one is 300×200 pixel; (c) A rectangle field of 600×300pixel, and a gray rectangle obstacle of 50×50pixel placed in the field; (d) Two rectangle fields, the left one is 300×300 pixel, the right one is 300×200pixel, and a gray rectangle obstacle of 50×50pixel placed in the field.

Table II summarizes that our proposed approach can significantly shorten the time for localization in both symmetric environment and featured environments compare with single robot localization. As to the successful rate, it depends on the type of environments. The improvement is obviously while localizing in symmetric environments.

TABLE II

COMPARE MULTI-ROBOT LOCALIZATION WITH SINGLE ROBOT LOCALIZATION IN SIMULATION EXPEIMENTS

Environment		t (s)	Time saving (%)	ε	Increasing of successful rate (%)
Symmetric	Single robot	368.02	70.6%	44%	32%
	Multi robot	109.56		76%	
Asymmetric	Single robot	31.4	28.3%	86%	3%
	Multi robot	22.485		89%	
Symmetric with obstacle	Single robot	33.24	27%	84%	4%
	Multi robot	24.25		88%	
Asymmetric with obstacle	Single robot	28.74	31.6%	92%	1%
	Multi robot	19.65		93%	

C. Study of parameter η

As we mentioned the value of η determines the stop point of each robot's localization which is specified by the minimum percentage of total particles contained in the largest cluster. In this group of experiments, we increase the value of η into 80%, while other parameters stay the same values with previous simulation experiments, to see how it can affect the performance.

TABLE III

COMPARISON OF MULTI-ROBOT LOCALIZATION UNDER TWO VALUES OF η

Environment	Multi robot	t (s)	Time increasing (%)	ε	Increasing of successful rate (%)
Symmetric	η=70%	109.56	18%	76%	2%
	η=80%	129.41		78%	
Asymmetric	η=70%	22.485	14.5%	89%	3%
	η=80%	25.75		92%	
Symmetric with obstacle	η=70%	24.25	16.9%	88%	4%
	η=80%	28.36		92%	
Asymmetric with obstacle	η=70%	19.65	8.5%	93%	1%
	η=80%	21.33		94%	

The results show that a large value of η will take more time to finish the localization process because it requires more information about its external environment to reduce the uncertainty of position estimation. In the mean time, the fact that more particles fall in the largest cluster indicates more likely the pose of representative of this cluster represents the true pose of the robot, which means the successful rate or effectiveness will be increased. However, there is a trade-off between efficiency and effectiveness controlled by η. If η is too big, it will take significantly longer time to localize itself while achieving a relatively small increase of successful rate. On the other hand, if η is too small, despite the rapid reduction of localization time, without guaranteeing the successful rate it will not make any sense to the localization.

V. Conclusion and Future Works

This paper presents a clustering based MCL algorithm for cooperative multi-robot localization, in which all robots moved simultaneously. Each robot maintains its own clustering based MCL algorithm, and communicates with each other whenever it detects another robot. The newly developed mechanism for the communication aims to achieve improve the efficiency and effectiveness of localization process. In addition, the characteristic of without fusion center and the instant communication between two detected robots allow our proposed approach scaling to large group of robots. Compare with single robot localization, experimental results performed in both real and simulated environments demonstrate the improvements in both efficiency and effectiveness of our proposed approach applied in cooperative multi-robot localization.

In the future work, we want to design a more robust way of movement based on already gathered information rather than the simple static path setting. We also want to test our approach on a large group of robots.

Soundscape Partitioning to Increase Communication Efficiency in Bird Communities

Abstract: Birds do not always vocalize at random, but may rather divide up sound space in such a manner that they avoid overlap with the songs of other bird species. In effect, a high degree of communication efficiency can be achieved by many simultaneously active vocalists that finely integrate songs with minimal overlap. We describe this phenomenon from several recordings at our principal study location, near Volcano, California. Among the most-studied models for conceptualizing and studying such de-synchronized systems come from scheduling algorithms in computer science, where internet protocols involve packets of information that are broadcast widely; any collisions between them will corrupt the colliding packets so that they need to be resent. We have simulated some of these methods that might be appropriate for the soundscape of bird communities. Some features of these de-synchronized depend on specifics of the algorithms used.

Keywords: Simulated evolution, DESYNC, sound space, resource partitioning, bird song

1 INTRODUCTION

Our laboratory is concerned with developing acoustic sensor arrays so that they will be useful for observing and analyzing bird diversity and behavior. In these studies we observed that birds do not always vocalize at random, but may rather divide up sound space in such a manner that they avoid overlap with the songs of other bird species.

For example, at our primary field site, in a mixed conifer-oak forest near Volcano, CA, we typically encounter 30+ species of birds during a short observation period. Not all of these species sing, but many do, and those who do sing appear to avoid collisions that would occur from singing at the same time. Table 1 shows the amount of time during which we observed 0, 1 or 2+ birds singing at the same time during a recording of approximately 3 minutes on the morning of June 22, 2010. The species singing at this time were: Spotted Towhee (*Pipilo maculatus*); Pacific-slope Flycatcher (*Empidonax difficilis*); Orange-crowned Warbler (*Vermivora celata*); Nashville Warbler (*V. ruficapilla*); Black-throated Gray Warbler (*Dendroica nigrescens*); Hutton's Vireo (*Vireo huttoni*); Red-breasted Nuthatch (*Sitta canadensis*); and Common Bushtit (*Psaltriparus minimus*). From the proportion of the total time each species sang, we can calculate the number of seconds we expect to be vacant (empty), monopolized by a single species, or occupied by the songs of 2+ species, given the species sing independently of each other. What we observed was that less time was vacant or occupied by 2+ species, and more time was monopolized, than expected by chance ($\chi = 14.1$, df = 2, $p < 0.001$).

We believe this avoidance of collisions in soundspace to be typical, if not universal. Others have observed such partitioning, in a variety of locations and species, including Wrentits (*Chamaea fasciata*) and Bewick's Wrens (*Thryomanes bewickii*) [2], Least Flycatchers (*Empidonax minimus*), and Red-eyed Vireos (*Vireo olivaceus*) [3], and a set of four species — Wood Thrush (*Hylocichla mustelina*), Eastern Wood Peewee (*Contopus virens*), Great Crested Flycatcher (*Myiarchus crinitus*), and Ovenbird (*Seiurus aurocapillus*) [4].

Table 1. The observation and expectation of singing behaviors in the recording in a mixed conifer-oak forest near Volcano, CA.

Time	Vacant (0)	Mono (1)	2+	Total
Expectation	102.4	64.8	18.8	186.0
Observation	92.4	85.8	7.9	186.0

In the study reported below we first describe a way to visualize sound space partitioning in a way that may prove to be generally useful, propose some general procedures that the birds might use to avoid collisions, then report on some evolutionary computer simulations that illustrate how these procedures might accomplish what we have observed. Attention is drawn to particulars that might permit experimental determination of just which procedures the birds employ in nature.

2 MATERIALS AND METHODS

Observations plotted in polar coordinates, as used in circular statistics, can help visualization of sound space partitioning. Birds typically sing repeated sequences of phrases, with only a short time between phrases. The entire sequence of phrases constitutes a song [1]. There is then a break of a few seconds, then a new song begins. Examples of some such songs for the species present are available at the web sites for xenon-canto (http://www.xeno-canto.org/) or Macaulay library (http://macaulaylibrary.org/).

Fig. 1 shows polar representations of recordings made at our study site during the mornings of April 19, 2010 (recording 10-21). In this figure the "driver" species was Black-headed Grosbeak (*Pheucticus melanocephalus*), BhGb, in red. Other species singing in the interstices are Orange-crowned Warblers, OcWa, in green and Nashville Warblers, NaWa, in blue. The mean vector of the distribution of singing events for each species is indicated by a bar. Time elapsed since the beginning of the period is indicated around the outside, and number of instances for each time interval by the inner circles. This recordings was made as described in [5], and is posted at our web site, http://taylor0.biology.ucla.edu/al/bioacoustics/. In this recording Black-headed Grosbeaks, were dominant. The average time between starting songs was approximately 7.7 seconds. This was taken as the period of the cycle, as represented around the circumference of the diagram. Time is represented as an angle, taken to be 0 at the beginning of the recording, then progressing to 360 at the end of each period, and then repeated.

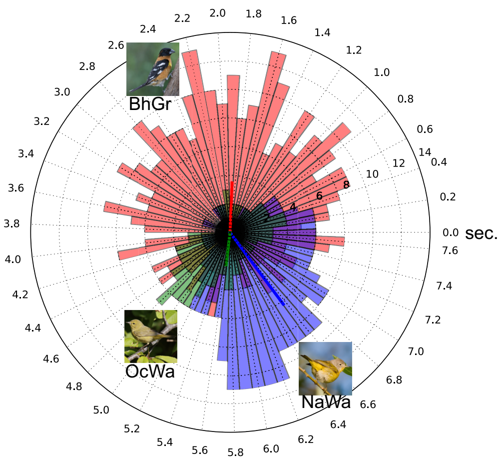

Fig. 1. Circular diagram of de-synchronized singing.

At each 0.1 sec in the recording, we checked whether a species was singing or not, accumulated the number of instances of singing, and represented this number as the radius length in the diagram. This was done separately for each species, then plotted. The average time between song starts usually gave the best representations, but some trial and error adjustments often helped clarity, and is, of course, necessary if there is no dominant species.

There are many procedures the birds might use to partition soundspace. The most-studied models for conceptualizing and studying such desynchronized systems come from scheduling algorithms in computer science, where internet protocols govern packets of information that are broadcast widely, and any collisions between them will corrupt the colliding packets so that they need to be resent. For this study we have simulated three procedures under the assumption that all individuals begin to sing with the shared period T if their songs do not overlap with other songs.

(a) "simple trial and error" If there is no overlap with the songs of others, then that individual will sing again exactly one time period later. But if the song of that individual overlaps at all with the song of another, then that focal individual will change slightly the time it starts its next song with a genetically determined probability p interpreted as its behavioral plasticity. Specifically, it begins to sing the next song with the interval of $T + dt(\ \ DT, DT)$, where $dt(x, y)$ is a random value generated from the uniform distribution on $[x, y]$. Otherwise, it will sing again exactly one time period (T) later.

(b) non persistent CSMA, or "back off" At its time to sing, the focal individual checks whether any other individuals are singing or not. If no one is singing, it begins to, and then decides to sing the next song one time period later. Otherwise (if other birds are singing), it delays its time to sing for the random time $dt(0, DB)$ with a probability p.

(c) DESYNC-based TDMA (Time division multiple access) or just **DESYNCH**. The basic idea of DESYNC algorithm [6] is that each agent modifies its own timing to fire so that it will occur midway between the preceding and the next firing events. We modified this slightly for birds. In our simulations each individual modifies its own timing to sing the next song with a probability p so that the timing gets closer to the relative distance ratio among the mid time point of the preceding (m_p), the focal (m_f) and the next song (m_n) becomes $m_f \quad m_p : m_n \quad m_f = SL_p + SL_f : SL_f + SL_n$ in the future songs. SL_f, SL_n and SL_p are the length of the focal, next and preceding songs respectively. The next timing to sing (t_n) is set in between this desired timing (t_d) and the scheduled timing with the period T (t_s) using an interpolation coefficient DD ($|t_d \quad t_n| : |t_n \quad t_s| = 1 \quad DD : DD$). Otherwise, it will sing again exactly one time period (T) later. This method can be shown to achieve full utilization of the available bandwidth, yet no global clock is required and the algorithm automatically adjusts to any number of participants. These acoustic interactions are conducted until the time reaches $R \quad T$.

For our simulations the population structure and evolutionary process were as follows: We assume S different species and the population of each species is composed of N individuals as shown in Fig. 2. In this example there are three species, with 4 individuals each. The whole population is randomly divided into the N groups of S individuals so that each individual participates in one group and each group includes exactly one individual for each species. The acoustic interaction is conducted among the members of each group independently in order to determine the fitness contribution of each individual. The fitness of each individual is taken to be the total duration during which the focal individual can sing solo (without interference).

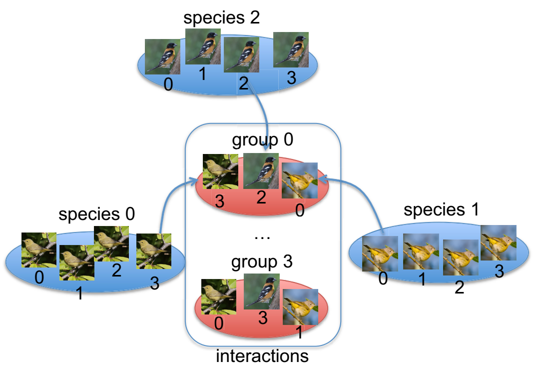

Fig. 2. Population and interaction model for evolution.

We modeled the evolution of the plasticity parameter p. Each individual has its own genetically-determined p that determines its behavior in acoustic interactions. The population of each species is evolved independently according to the genetic algorithm based on selection and mutations. The selection of offspring in the next generation is based on a "roulette wheel selection" according to fitness. For each gene of offspring, a mutation occurs with a small probability p_m, which adds a small random $dt(\quad DM, DM)$ to the current value.

3 RESULTS AND DISCUSSION

For each procedure we conducted experiments with various settings of T for 500 generations using $N = 80, S = 5, R = 30, DT = 7.0, DB = 13.0, DD = 0.5, DM = 0.1$ and $p_m = 0.01$. We assumed the species-specific length of song of the i-th species $SL_i = \{1, 2, 4, 8 \text{ and } 16\}$. The initial population was generated with initial values of p sampled from the uniform distribution over $[0, 1]$. We focused on the effects of T on evolution because it determines the degree of congestion in the acoustic space. Fig. 3 shows the average p in the last generation with the three different temporal avoidance mechanisms. We see that the evolutionary process of plasticity is strongly dependent on the basic temporal avoidance mechanisms and the setting of T.

In the case of (a) "simple trial and error", the plasticity of all species was high when T was large enough. This means that species will generally evolve to avoid temporal overlap of songs in less crowded acoustic spaces. As T decreased, the plasticity of the species with the longest song tended to be small while those of the other species remained high. In other words, the species with the longest song typically evolves to become dominant – what we term the "driver species." The driver species does not change the timing of its song to avoid overlap very much, but keeps its original periodicity, while species with shorter songs adapt to fit into the remaining time segments. Fig. 4 shows examples of interactions among evolved species in three groups with the different temporal avoidance mechanisms when $T = 42$. In this case, we see that the shorter songs randomly fluctuated several times, but they finally fit into the rest of the space left by the driver species with the longest song. This phenomenon can be explained by focusing on the benefit and cost of the adopted temporal avoidance behaviors. In this case, the benefit is to be able to resolve existing overlaps in the future interactions. However, this avoidance can fail and yield another overlap with other songs because of the randomness of the trial and error procedures. Because the effect of this cost is approximately proportional to song length, the species with the longest song is least likely to make timing adjustments and, instead, the species with short songs will make the behavioral adjustments to fit into the soundscape with minimal overlaps.

In the case of (b) "non persistent CSMA", we see that the plasticity of shorter songs converged to higher values as T decreased, while that of the longest song evolved to relatively smaller values although this tendency was not so dramatic as in the previous case. We see from Fig. 4 (b) that the individuals successfully converged to the state with no overlaps by actively delaying their timing to sing in a counterclockwise fashion. The main reason for the evolution of the smaller plasticity of the longest song is not due to the same reason that was observed in case (a). In case (b), the benefit of temporal avoidance is to be able to avoid the overlap with other songs being currently delivered. This benefit is essential for the species with shorter songs because their songs are often completely masked by other longer songs if they do not actively avoid overlap, and vice versa. However, delayed song delivery means that individuals risk losing chances to sing within a limited, finite time span. Thus, the species with the longest song will evolve low plasticity to reduce the cost of avoidance behavior and maximize song delivery opportunities.

In the case of (c) "DESYNC", we see that the plasticity of all species evolved to be high in all conditions of T although p of the longest song was slightly smaller than that of others. This is due to the fact that the p of the longest song evolved to low plasticity in a small number of trials at higher T, implying that somewhat reduced p could be adaptive in those cases. Fig. 4 (c) shows that all individuals actively adjusted their timing to sing in both clockwise and counterclockwise

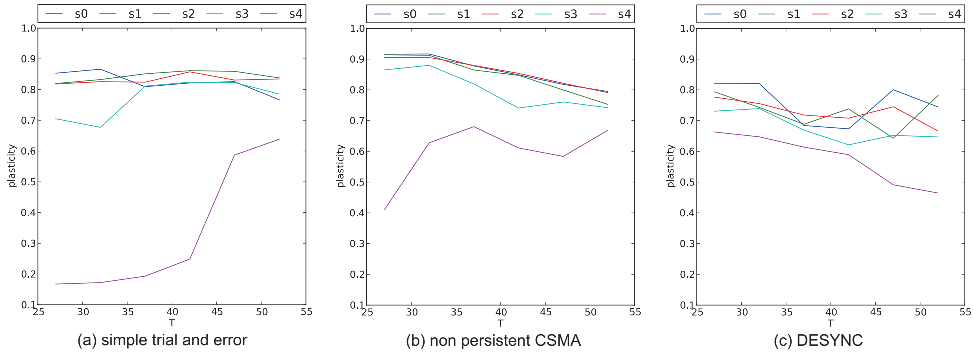

Fig. 3. The average p in the last generation with the three different temporal avoidance mechanisms. Each value is the average over 15 trials.

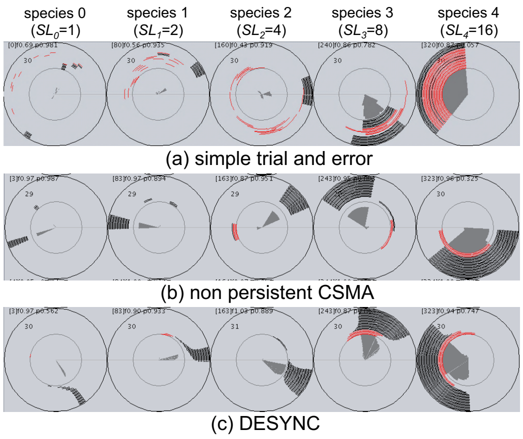

Fig. 4. Examples of interactions with different temporal avoidance procedures when T=42. The five circular diagrams correspond to a group for acoustic interactions. Each diagram represents the singing behavior of an individual. The distribution of its singing events is represented in the inner area in the same way as represented in Fig. 1. The arcs in the outer area show the distribution of songs over the circular time-line where each succeeding period T is arranged from inner- to the outer-most position. Red or black arcs are the songs with or without overlaps, respectively.

manners, and as a result, the population quickly converged to the state with no overlaps. This implies that our modified DESYNC algorithm is adaptive and has almost no cost for adjustment processes. Thus, we did not observe significant effects of the differences in the length of songs on the evolution of the behavioral plasticity of individuals.

4 CONCLUSIONS

We discussed sound space partitioning to increase communication efficiency in bird communities. We described this phenomenon from several recordings, using a way to visualize sound space partitioning based on a circular diagram. We also proposed some general procedures that the birds might use to avoid collisions, then reported on some evolutionary computer simulations that illustrate how the procedures might accomplish what we have observed. The dynamics of soundscape partitioning that emerge as behavioral plasticity evolves to minimize interspecific song overlap are illuminated with our simulation procedures, which can be used to elucidate the communication protocols employed by birds in complex, real-world situations.

Abstract: In the RoboCup MSL (Middle Size League), each robot should be autonomous and have fundamental abilities like obstacle avoidance, path planning, and cooperative behavior. Self-localization is one of the most basic and important functions for mobile robots, especially, multirobot system with cooperative behavior. We aim at improvement of self-localization accuracy of each robot of multirobot system by information sharing. To enhance the robot position accuracy, the soccer ball is used as the common landmark that just one exists in the playing field. In general, measured data, such as distances and angles to the white lines on the field, the ball, have measurement errors in the actual environment, so that we assume that the existence possibility of landmark position follows the Gaussian distribution. In our multirobot system, all robots share the group robot information such as estimated self-location and likelihood, distance and angle to the ball, role (defender, forward) via wireless LAN. Each robot evaluates the position likelihood of the landmark based on the landmark's existence probability. Then each robot corrects its position using fed-back the landmark position. In order to evaluate the efficiency of the proposed method in the real environment, the estimated self-location has been evaluated through experiments using the soccer robots "Musashi".

Keywords: *Multirobot System, Self-Localization, Information Sharing, RoboCup Middle Size League*

1 INTRODUCTION

For autonomous mobile robots, self-localization is one of the most fundamental and important information. Especially, when a multirobot system performs cooperative actions in real-time and actual environment, the importance of self-location increases. In the RoboCup Middle Size League (RoboCup MSL), the self-localization information of each robot is also important information for achieving the cooperative behavior [1][2].

In this research, the RoboCup MSL is selected as the target research platform for development and evaluation of multirobot system and cooperative behaviors, where maximum five robots from a team play soccer game and the collaborations with teammate robots such as pass and role change are inevitable to keep the rules. In the RoboCup MSL, active sensors like laser scanner are also allowed to obtain the surrounding environment, however, the playing field is the flat and simple symmetric environment with few landmark objects and often occupied by many mobile robots, therefore our robots obtain the environmental information mainly from an omni-vision sensor. In the beginning period of MSL, many variations of robots exist and many kinds of sensors are mounted, recently almost robots have an omni-vision system and an omni-directional mobile mechanism to be a holonomic system for easy motion planning [2-5].

Most of MSL robots estimate self-locations and the ball position from images of omni-vision systems using the white lines' position on the field and colored object position [6-8]. In our multirobot system, the distances to white lines are compared with the field model using particle filter and the self-location of each robot is estimated [8-10]. The absolute ball position is obtained by adding the robot self-location and the relative position of the ball from the robot.

We propose a cooperative self-localizing method which use the ball on the soccer field as the common landmark for all teammate robots, and self-locations are corrected by using the estimated absolute ball position by all robots. The proposed system represents the ball position by the existence probability functions for all robots depending on the distance, where the function show high value for the ball-closed robot and low for the robot far from the ball. By combining the probability functions, the ball existence probability map is generated and the proper ball position is estimated. Then, the robot positions and directions are also modified using the estimated ball position.

In experiments, the efficiency of the proposed method with group robot information sharing was evaluated using multirobot system RoboCup MSL by comparing the ball position and robots positions information sharing in real environment, and the experimental results show good improvement of self-locations of Musashi robots.

2 SINGLE ROBOT LOCALIZATION

In the proposed method, each robot estimates its position and direction by the Monte Carlo Localization (MCL) based on the geomagnetic data and the relative distance between the robot and white field lines [6-12]. The origin of the field map is the center of the field and the field is modeled in Cartesian coordinate taking *x* axis to the own goal direction.

The robot's state at time step *t* is represented by $\boldsymbol{x}_t = [r^x_t, r^y_t, {}^a\theta_t]^T$ which consists of its position (r^x_t, r^y_t) and heading ${}^a\theta_t$. The posterior probability $p(\boldsymbol{x}_t|\boldsymbol{y}_{1:t-1})$ is calculated from $\boldsymbol{x}_t$ and time series of observed data $\boldsymbol{y}$. Here, $\boldsymbol{y}_t$ at time step *t* includes 60 relative distances to the closest white line every 6 degrees. In the MCL method, the probability distribution is represented by a set of *N* particles. In our application, each particle has $\boldsymbol{x}_t$ and $\boldsymbol{y}_t$ and the conditional probability $p(\boldsymbol{x}_t|\ \boldsymbol{x}_{t-1},\ \boldsymbol{u}_{t-1})$ is specified by the previous state $\boldsymbol{x}_{t-1}$ and control input $\boldsymbol{u}_{t-1}$. Here, we use odometory data as $\boldsymbol{u}_{t-1}$. In order to apply MSL to self-localizing problem, we assume that the self-location probability follows the Markov decision process, and the posterior probability of current robot state is obtained by the following equation.

$$p(\boldsymbol{x}_t|\boldsymbol{y}_{1:t-1}) = \int p(\boldsymbol{x}_t|\boldsymbol{x}_{t-1}, \boldsymbol{u}_{t-1}) \cdot p(\boldsymbol{x}_{t-1}|\boldsymbol{y}_{1:t-1}) d\boldsymbol{x}_{t-1} \quad (1)$$

Next, as shown in eq.(2), $p(\boldsymbol{x}_t|\boldsymbol{y}_{1:t})$ is updated based on the Bays theorem using likelihood $p(\boldsymbol{y}_t|\boldsymbol{x}_t)$ which is represented as the difference between line distances in each particle and observed data.

$$p(\boldsymbol{x}_t|\boldsymbol{y}_{1:t}) = \frac{p(\boldsymbol{y}_t|\boldsymbol{x}_t) \cdot p(\boldsymbol{x}_t|\boldsymbol{y}_{1:t-1})}{p(\boldsymbol{y}_t|\boldsymbol{y}_{1:t-1})} \quad (2)$$

The robot orientation is estimated from $\boldsymbol{x}_t$, however, the RoboCup MSL environment consists of symmetric and simple surfaces and always two candidate positions exist. That is, MCL has the possibility to select a wrong robot position in the MSL soccer field, called "Kidnapped Problem [13]". To help the problem, the geomagnetic sensor is utilized to have the robot direction. The predicted robot position is calculated by weighted average based on $\boldsymbol{x}_t$ and $p(\boldsymbol{x}_t|\boldsymbol{y}_{1:t})$ as a weight. The self-localization process calculates the estimation iteratively. When the likelihood of estimated position from MCL is lower than a certain threshold (low reliability), the position from dead-reckoning method is adopted.

3 COOPERATIVE SELF LOCALIZATION

In our system, the self-localization is detected based on the visual information and wheel encoder data. Therefore the accuracy of self-localization depends on lighting condition, occlusions by opponent robots, and wheel slipping. In this paper, we consider the feature of multirobot system in RoboCup MSL, and propose a cooperative self-localization method based on information sharing among multirobots. The proposed method is realized by following steps.

Step 1. All robots find the ball and set as the common landmark.

Step 2. All robots share the ball position and self-position via wireless LAN.

Step 3. All robots estimate the proper ball position based on the shared information

Step 4. Using the estimated landmark (ball) position, each robot updates its position.

In this paper, the proper ball estimation of Step 3 is described "Landmark Estimation", and we call the estimated ball position by multi robots "the proper ball position" in followings. Self-position updating of Step 4 is described "Cooperative Self-Localization."

3.1 Landmark Estimation

In RoboCup MSL, many robots has omni-directional camera as an external sensor [5-8]. In this study, we assumed that the robot is equipped the omni-directional sensor and each object position is calculated using the own position and relative distances and angles between the robot and objects.

In general, the localization accuracy of object by the omni-directional camera depends on the distance from camera. In this process, each robot calculates the ball existence probability p^i_d by assuming the Gaussian distribution shown in eq.3. The variables p^x and p^y indicate the *x* and *y* coordinate of an arbitrary point on the soccer field, $\overline{m^i_x}$ and $\overline{m^i_y}$ do the *x* and *y* coordinate of the observed ball position from *i*-th robot ($\boldsymbol{m}^i=[m^i_x, m^i_y]^T$). Here, $\overline{m^i_x}$ and $\overline{m^i_y}$ are calculated as weighted average during *n* steps as shown in eq.4; we used the time-depending weight w_t. The parameters σ^i_d is the weighted variance parameters during *n* steps as shown in eq.5; $\overline{d^i}$ is the weighted average of the relative distance between the *i*-th robot and the ball from eq.6.

$$p^i_d(p^x, p^y) = \prod_{k=x,y} \frac{1}{\sqrt{2\pi\sigma^i_d}} \exp\left(-\frac{\left(p^k - \overline{m}^i_k\right)^2}{2\sigma^i_d} \right) \quad (3)$$

$$\overline{m}^i_{x,y} = \sum_{t=1}^{n} m^i_{x,y}(t) \cdot w_t \Big/ \sum_{t=1}^{n} w_t \quad (4)$$

$$\sigma^i_d = \sum_{t=1}^{n} \left(d^i(t) - \overline{d^i} \right)^2 \cdot w_t \Big/ \sum_{t=1}^{n} w_t \quad (5)$$

$$\overline{d^i} = \sum_{t=1}^{n} d^i(t) \cdot w_t \Big/ \sum_{t=1}^{n} w_t \quad (6)$$

The robot direction is estimated based on the MCL and heading sensor data, however the heading sensor data includes noise from magnetic distortion, so that the existence probability of the ball position p^i_s regarding magnetic compass is set to the Gaussian distribution in eq.7. As shown in Fig. 1, the parameter θ^i shows the angle between two lines; one line is from the *i*-th robot to the ball, and the other line is from the *i*-th robot to arbitrary point. The parameter r^i is the distance from the *i*-th robot to the arbitrary point, and l^i is the length of the arc; the center of the arc is the *i*-th robot position.

The parameter V^i is the weighted variance parameter regarding to the relative ball angle $\overline{\theta^i_{rel}}$ in robot coordinate during n steps as follows in eq.8. $\overline{\theta^i_{rel}}$ is calculated as weighted average during n steps as shown in eq.9. In the eq.10, we define that the variance for p^i_s is sum of the variance of heading sensor θ_{th} and V^i which regarding time. The ball existence probability is distributed along the circular arc, and the probability density takes the maximum value on the straight line L from the robot to the ball.

$$p^i_s\left(l^i\right) = \exp\left(-\frac{{l^i}^2}{2{\sigma^i_s}^2}\right) \quad (7)$$

$$V^i = \sum_{t=1}^{n}\left(\theta^i_{rel}(t) - \overline{\theta^i_{rel}}\right)^2 \cdot w_t \Big/ \sum_{t=1}^{n} w_t \quad (8)$$

$$\overline{\theta^i_{rel}} = \sum_{t=1}^{n} \theta^i_{rel}(t) \cdot w_t \Big/ \sum_{t=1}^{n} w_t \quad (9)$$

$$\sigma^i_s = r^i \cdot \sin\left(\theta_{th} + V^i\right) \quad (10)$$

In the proposed system, the conclusive ball existence probability p^i_{all} is calculated as the product of p^i_d and p^i_s in eq.11. Here, M is the number of robot in our team. Finally, we assume that the proper ball position p^i_{all} is the highest on the soccer field.

$$p^i_{all}\left(p^x, p^y\right) = \frac{1}{2M}\sum_{i=1}^{M}\left\{p^i_d\left(p^x, p^y\right) + p^i_s\left(l^i\right)\right\} \quad (11)$$

3.2 Cooperative Self-Localization

When the robot position has error, the observed ball position will be estimated far from the true ball position. It is desirable that the estimated robot position is adjusted near the true robot position by using the landmark, the ball position, so as to fit the observed ball position to the proper ball position. In the proposed system, we introduced an updating rule for ball position as shown in eq.12. α^i_d means the coefficient for updating the ball position based on the

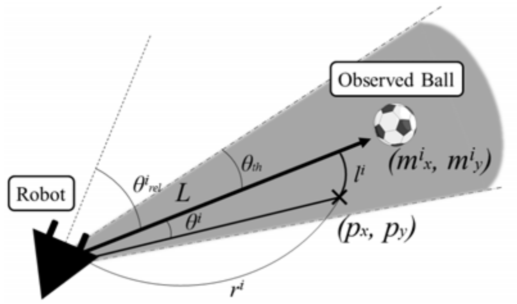

Fig. 1. Definition of existence probability p^i_s

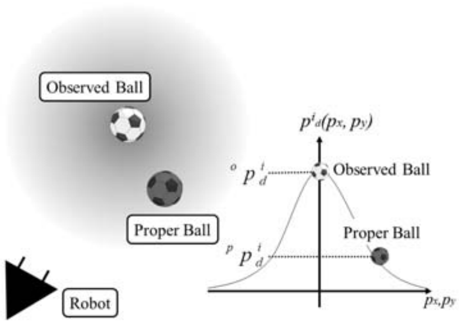

(a) (b)

Fig. 2. Updating coefficient by parallel translation based on $^o p^i_d$ and $^p p^i_d$.

ball existence probability as following eq.13. γ^i_d is dumping factor which follow the feature of omni-directional camera as shown in eq.14. $d_{\min}$ means minimum relative distance between the robot and ball, and we set 0.4 as a $d_{\min}$ in this experiment.

$$\Delta \boldsymbol{m}^i = \alpha^i_d \cdot \gamma^i_d \cdot (\boldsymbol{m}^i_p - \boldsymbol{m}^i_o) \quad (12)$$

$$\alpha^i_d = \frac{{}^o p^i_d - {}^p p^i_d}{{}^o p^i_d} \quad (13)$$

$$\gamma^i_d = \exp\left(d_{\min} - d^i(t)\right) \quad (14)$$

The robot position is also revised by parallel translation based on p^i_d and rotational translation based on p^i_s. $\boldsymbol{R(\theta)} \in \boldsymbol{R}^{3\text{x}3}$ is rotational matrix, and β^i_d means the coefficient for updating the robot angle based on p^i_s. θ_{pro} means the direction of the proper ball position in the robot coordinate. $^o p^i_s$ and $^p p^i_s$ are the observed and the proper ball position reliability regarding the ball angle.

$$\boldsymbol{x}_{t+1} = \boldsymbol{x}_t \cdot \boldsymbol{R}(\Delta\theta^i) + \left[\Delta \boldsymbol{m}^{i^T}, \Delta\theta^i\right]^T \quad (15)$$

$$\Delta\theta^i = \beta^i_d \cdot \left(1 - \gamma^i_d\right) \cdot \left(\theta_{pro} - \theta^i_{rel}\right) \quad (16)$$

$$\beta^i_s = \frac{{}^o p^i_s - {}^p p^i_s}{{}^o p^i_s} \quad (17)$$

Considering the parallel translation updating, let us consider the situation as shown in Fig. 2. Figure 2-(a) shows the observed ball and the proper ball, and the robot calculates the ball position reliability to take high value around observed ball position. ${}^{o}p^{i}_{d}$ and ${}^{p}p^{i}_{d}$ in Fig. 2-(b) are the probabilities of the observed and the proper ball position. Equation 17 is derived in the same way with the position updating. Finally, the robot state is updated by eq.15.

4 EXPERIMENTAL RESULTS

We evaluated the performance of the proposed system used soccer robot "Musashi [14, 15]" as shown in Fig.3 in real environment. In the experiment, five robots are set in the fixed positions as shown in Fig. 4. The ball moves from A(0.00, 0.00) to B(8.50, 0.00) at a speed of 3.0[m/s]. The color calibration was set by human operator, and the lighting condition was constant during experiment. In one experiment, 80 data of self-localization and the absolute ball position were recorded during the approximately 3.0[sec]. Figure 4 shows the position of each robot and the ball on the soccer field. The positions are goalkeeper:(9.00, 0.00), field-player1:(6.00, 3.00), field-player2:(3.00, 3.00), field-player3: (3.00, -3.00) and field-player4: (6.00, -3.00). The direction of the each robot was taken to the opponent goal. In consideration of the time delay in communication between robots, the position information of goalkeeper and the provided position information from field-players to goalkeeper were used for the experiment. Table 1 shows absolute errors of the proper ball position and observed ball position. Table 2 shows absolute robot state errors of self-localization by the single robot (MCL only) and multi robot (Cooperative Self-Localization).

In evaluation of the ball position, we focused on the y axis error e_{bd} of the ball and evaluated by eq.18. Here, N means data amount of self-localization and the absolute ball position, and m^{tr}_{y} and ${}^{n}m^{i}_{y}$ is proper y position of the ball and y position of observed or estimated ball.

$$e_{bd} = \frac{1}{N}\sum_{n=1}^{N}\sqrt{\left(m_y^{tr} - {}^{n}m_y^{i}\right)^2} \qquad (18)$$

The absolute robot state errors e_{rp}, e_{ra} are evaluated by eq.19 and eq.20. r^{ty}_{x}, r^{ty}_{y} and θ^{r} is correct robot state, respectively. And also, ${}^{n}r^{i}_{x}$, ${}^{n}r^{i}_{y}$ and ${}^{n}{}_{a}\theta^{i}$ means robot state at time-step n.

$$e_{rp} = \frac{1}{N}\sum_{n=1}^{N}\sqrt{\left(r_x^{tr} - {}^{n}r_x^{i}\right)^2 + \left(r_y^{tr} - {}^{n}r_y^{i}\right)^2} \qquad (19)$$

Table 1. The result of landmark estimation

	No.1 [m]	No.2 [m]	No.3 [m]	No.4 [m]	No.5 [m]	Proposed Method [m]
e_{bd}	1.09	0.91	0.33	0.46	0.61	0.39
SD	0.82	0.31	0.23	0.16	0.44	0.20

Table 2. The result of cooperative self-localization

	Single Localization		Multi Localization	
Position[m]	e_{rp}	SD	e_{rp}	SD
	0.36	0.09	0.34	0.09
Angle[deg]	e_{ra}	SD	e_{ra}	SD
	25.05	9.62	14.54	12.04

$$e_{ra} = \frac{1}{N}\sum_{n=1}^{N}\sqrt{\left(\theta^{tr} - {}_{a}^{n}\theta^{i}\right)^{2}} \qquad (20)$$

In table 1, the absolute observed ball position error of goalkeeper included 1.09[m] in average, and also standard variation (*SD*) was 0.82[m]. As shown in Fig.5, the observed ball position error was reduced when the ball moved until near the robot. The absolute ball position error of landmark estimation showed 0.39[m] in average and *SD* was 0.20[m]. This result indicates the landmark estimation could reduce the absolute ball position error than the absolute observed ball position error of goalkeeper. Table 2 shows the absolute robot state error of cooperative self-localization was smaller than the single robot localization. The absolute robot position error of single robot localization was 0.36[m] in average and *SD* was 0.09[m], and also the aboslute angle error was 25.05[deg] in average and *SD* was 9.62[deg]. In the results of cooperative self-localization, the absolute robot position error was 0.34[m] in average and *SD* was 0.09[m], the absolute angle error was 14.54[deg] in average and *SD* was 12.04[deg]. This result indicates the robot state was guided to the proper robot state, however the standard variation of the observed information affects the result of cooperative self-localization.

5 CONCLUSION

We proposed a cooperative self-localization method based on group robot information sharing using the landmark position and implemented the proposed method to a multirobot system “RoboCup MSL robots”. The performance of the poposed method has been evaluated using five autonomous mobile robots. This experimental results show that the ball estimation based on the information sharing increases the reliability of ball existence. In RoboCup MSL environment, it is mentioned that the reliable ball position can be shared with the robot which cannot observe a ball due to increasing the reliability of the ball position. In addition, cooperative self-localization can adjust the robot positions to the proper position.

As a future work, we apply the proposed method to realize the cooperative behaviors such pass, drible, and shoot.

Abstract: The paper focuses on proposing a dual layered, multi agent based control system for distributed control of a microgrid aimed at intentional islanding. The architecture consists of two layers; primary layer and secondary layer. The primary layer includes a User agent, a Distributed Generator (DG) agent and a Control agent. The secondary layer consists of a Low Voltage (LV) agent and a Load agent. The Control agent is capable of supervising the secondary layer agents. The proposed multi agent based control architecture is developed using the JADE platform and it is used to control a microgrid simulated in MATLAB/SIMULINK. In order to validate the effectiveness of the proposed method, investigations are carried out for islanding scenarios simulated on the test network. The results of this study show the capability of developing a reliable control mechanism for islanding operation of microgrids based on the proposed concept.

Keywords: distributed control, intentional islanding, microgrid, multi agent systems.

1 INTRODUCTION

Legacy power distribution systems are facing a tough challenge in meeting the needs of the rapidly evolving electricity market. Time is ripe for a smarter grid capable of meeting the present and future power delivery requirements. The looming dangers of climate change is also demanding a paradigm shift from large scale fossil fuel based sources towards small scale lower emission systems. The incorporation of smaller distributed generation (DG) units with maximum renewable energy penetration is vital in meeting all these demands.

This requires the ability to handle active generation and loads, which had not been addressed in existing legacy system designs. Smaller microgrids comprising local generation is a concept put forward to cater this requirement. These microgrids can be operated either in island mode, where the local loads are fully supplied by the local generation, or in grid connected mode, where the microgrid is either exporting or importing power from the main grid.

With the local generation and loads coming into the picture, local distributed control is essential for the local grid stability. Microgrid can survive from an upstream outage in the main grid by switching to island mode and maintaining supply to the most critical local loads. Load shedding has to be carried out rapidly when the microgrid is switched to island mode as the local generation capabilities might be limited.

In order to provide these local distributed control capabilities, development of distributed control systems are essential. Multi Agent Systems (MAS) is a technology coming forward in this aspect. MAS have been developed for a wide range of applications in power systems [1]. The use of MASs in microgrid applications has been evolving over the last decade with considerable amount of work being carried out regarding distributed control applications for microgrids [2].

This paper proposes a novel dual layered MAS capable of distributed control of a microgrid. The MAS is developed in JADE platform and it is used to control a microgrid simulated in MATLAB/SIMULINK. A brief outline of micro grids is presented in section 2. An overview of multi agent systems is presented in section 3. The proposed dual layered multi agent system architecture is presented in section 4. Section 5 describes the simulations carried out and their results. Finally the conclusions are given in section 6.

2 OUTLINE OF MICROGRIDS

Microgrids can be created by embedding small-scale conventional generation units or Non-Conventional Renewable Energy Sources (NCRES) to existing electrical infrastructure. These NCRES can be mini-hydro, solar photo-voltaic (PV), wind, geo-thermal, small internal combustion (IC) engines, biomass or waste-to-energy systems. Such embedded systems will provide the microgrid with DG capabilities. A conceptual model of a microgrid is presented in Fig. 1.

Once an upstream disturbance takes place on the main grid, the microgrid can separate from the main grid at the point of common coupling and isolate the local loads from any outage, providing a higher level of service, with minimum effect to the stability and the integrity of the main grid. This capability of intentional islanding will deliver a higher reliability than legacy power systems [3]. Thereafter, the microgrid has to manage the local loads to make sure that the most critical loads are supplied by the available limited local capacity. This would require priority based load shedding.

3 OVERVIEW OF MULTI AGENT SYSTEMS

Multi agent systems are complex systems composed of several autonomous agents with only local knowledge and limited abilities but are able to interact in order to achieve a global objective [1]. Their ability to act as a container for conventional control methodologies as well as artificial intelligent based techniques and expert systems has become an additional advantage in building hybrid controllers in microgrid.

A MAS in essence is an abstraction of the role of agents in real life into intelligent control systems. These agents are able to act as autonomous social entities which react to changes in their environment and take intuitive actions in order to realize their individual goals. The aim of a multi agent based control system is to apply this individual goal seeking in a manner such that the overall target required by the user is achieved efficiently and effectively as possible.

Since Fast communication facilities such as fiber-optics, 3G, GSM/GPRS have become an integrated part of power systems [4], it is easier and more feasible to integrate multi-agent systems into power system applications.

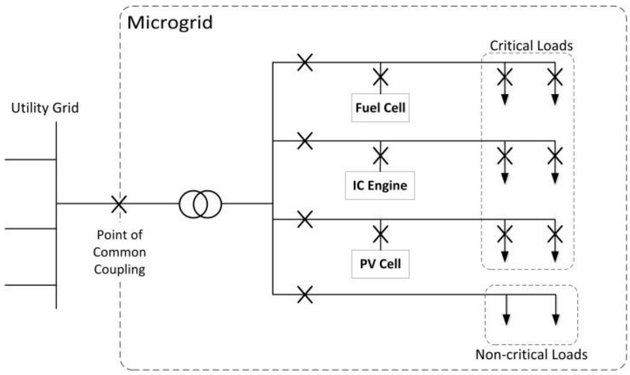

Fig. 1. Conceptual model of a microgrid

In a microgrid, an individual intelligent agent can be assigned to each entity (circuit breaker, generation unit, loads, users etc.). This assignment determines the architecture of the MAS. Several different multi agent architectures have been presented in [5]-[8].

4 DUAL LAYERED ARCHITECTURE OF MULTI AGENT SYSTEM

Fig. 2 shows the conceptual design of the proposed dual layered control architecture for microgrids. The MAS system is developed using the JADE platform [9]. The model presents a dual layer distributed control architecture. The primary layer comprises of three major agents; DG Agent, User Agent and Control Agent. The three major agents will be tasked with sensing and controlling the components of the microgrid. The DG agent will collect the information related to the DG such as; availability, connection status, power rating, energy source availability and cost of energy. The control agent is in control of a secondary layer comprising of a Load agent and a Low Voltage (LV) agent, overseeing the load control and microgrid connection control capabilities.

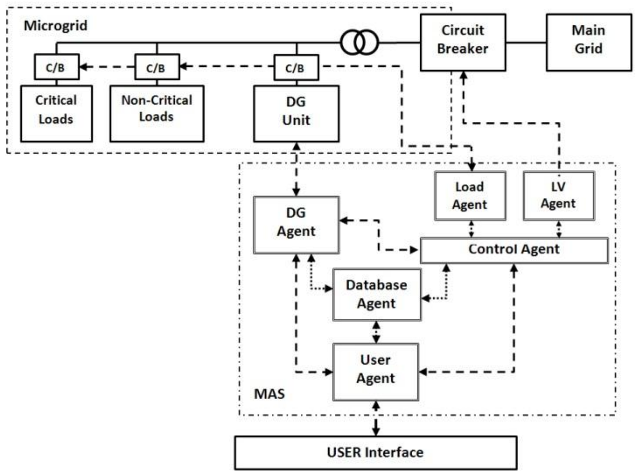

Fig. 2. Dual layered MAS architecture

During an upstream fault, the LV agent will island the microgrid, by tripping the circuit breaker at the point of common coupling, if the Control agent allows it. During island operation the load shedding will be taken care of by the Load agents to ensure that power is delivered to the most critical loads on the priority basis set by the Control agent. This will be implemented by Load agents opening circuit breakers at each of the controlled local loads.

The User agent behaves as the gateway for the user to interact with the system, to obtain real-time information and set system goals. A utility agent acting in the form of a database agent is utilized to store system information and the data and messages shared between the agents. The database agent will also be the access point for data for all the agents and users.

The control agent will be the center of the primary layer holding influence over the DG agent and controlling the LV and Load agents. The control flow chat followed by the control agent is given in Fig. 3. The operation of the control agent during the detection of an upstream outage is described in the next section.

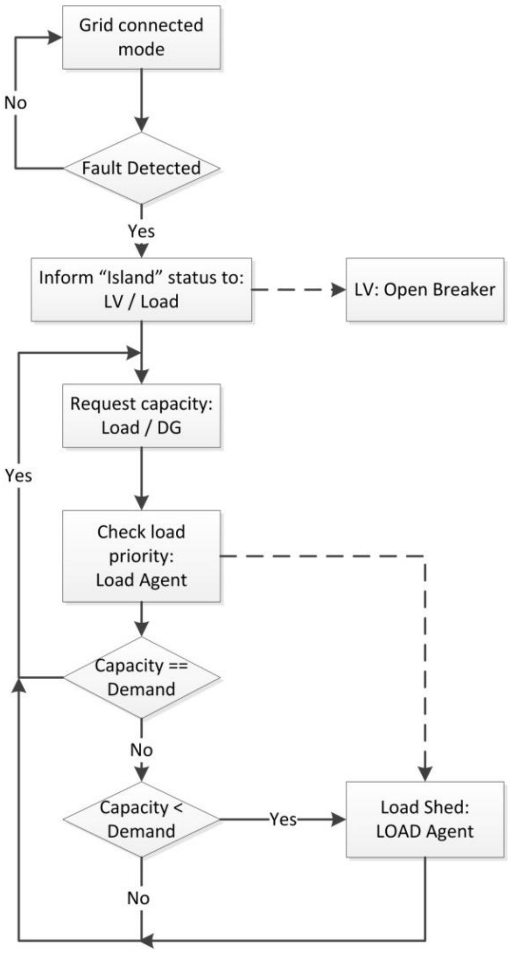

Fig. 3. Control flow chart of Control agent

5 SIMULATION AND RESULTS

The microgrid test bed used for the simulations (Fig. 4) consists of an embedded generator, acting as a DG unit, supplying part of the local demand, and several critical and non-critical loads. It is assumed that the DG unit can operate at full capacity without fuel limitations during any outage. This simulation test bed is modeled using MATLAB/SIMULINK. An external TCP/IP server [10] is used to connect the MAS to the simulated test bed.

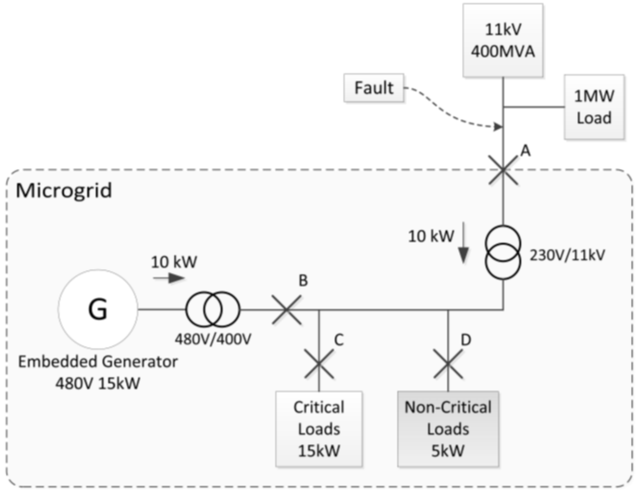

Fig. 4. Microgrid simulation model

The objective of the test setup is to demonstrate the ability of the proposed MAS to island the microgrid after an upstream fault is detected. Initially the microgrid is operating in the grid-connected mode, with the embedded generator is supplying only part of the local loads while the rest is supplied by the utility grid. The demands supplied by the DG and the grid are depicted in Fig. 4. At the beginning of the simulation breakers A, B, C and D are all closed.

While the microgrid is in grid connected mode and upstream fault is introduced at 0.05 s as seen in Fig. 5 and is switched to island mode thereafter. Line-to-line voltages are measured from points C and D shown in Fig. 4.

5.1 Grid connected mode

While the microgrid is in grid-connected mode, the total demand is 20 kW, with 15 kW critical loads and 5 kW non-critical loads. During the grid-connected mode the embedded generator only provides 10 kW output, 50% of the total demand. Another 10 kW is required from the main grid to supply the microgrid.

5.2 Transition period

When the upstream outage is detected at t = 0.05 s the control agent informs the LV agent and the Load agents to switch to island mode operation. Upon receiving the islanding order the LV agent trips the main circuit breaker A, at the point of common coupling, isolating the microgrid from the utility (Fig.5(c)). The Control agent then queries the DG agent and the load agents regarding their available capacities the DG can provide to the microgrid and the power requirements of the connected loads.

As the total load of 20 kW exceeds the available maximum capacity of 15 kW, the control agent commands the load agents to shed the 5 kW non-critical loads to match the DG capacity. Soon as the microgrid is put to island mode the supply to the critical loads is maintained (see Fig. 5(a)). The load agent at the non-critical loads sheds them from the system by opening breaker D (see Fig. 5(b)).

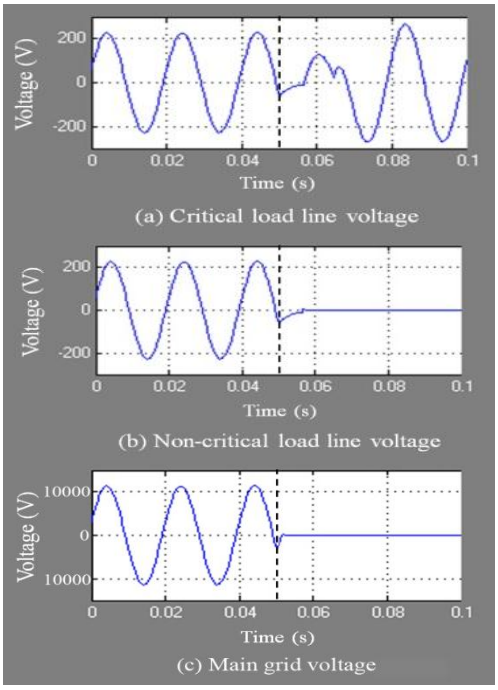

Fig. 5. Simulation results during intentional islanding. (a) Line to line voltage across critical load at 'C', (b) Line to line voltage across the non-critical load at 'D', (c) Line to line voltage at breaker 'A'.

5.3 Islanded mode

At t=0.05s the microgrid is separated from the main grid and the load agents balance the local demand. After the microgrid switches to island mode the total local demand is met by the embedded generator supplying 15 kW.

All agent operations are carried out rapidly, from detecting fault, opening the main breaker, connecting the local source and shedding loads, to stabilize the microgrid within 0.02 s. Therefore the system is able to disconnect from the main utility grid and maintain the supply to the critical loads without suffering a brownout and/or blackout.

6 CONCLUSION

A dual layered MAS for intentional islanding operation of microgrid is proposed in this paper. The agent architecture was developed using the JADE platform. Time domain simulations were carried out using a test system simulated in MATLAB/SIMULINK. The test bed was simulated for 0.1 s with the introduction of an upstream fault at 0.05 s. the MAS was able successfully restore supply within 0.02 s to the critical loads by islanding the microgrid and shedding non-critical loads. The results show the capability of the Multi Agent System to safely island and maintain the supply to its critical loads. These results validate the effectiveness of the MAS in controlling DG units to protect and control a microgrid. In the future the MAS will be implemented on a physical test bed to further validate the results.

Abstract: This paper proposes a framework of a distributed kinematics process model applied to multi-link robots. In the framework, hardware modules which consists of joints and links are defined as joint components of robotic systems, then kinematics models are composed of a set of the local kinematics Agents (LKAs) which are software module to compute the localized direct and inverse kinematics. Kinematics of robotic systems is resolved by the localized kinematics calculation of LKAs for an end effecter to a target position and an information exchange among LKAs. The proposed framework has been applied to case study of the inverse kinematics problems of 7 degree of freedom redundant multi-link robot manipulator.

1 INTRODUCTION

The latest decade, practical use of robot technologies has been anticipated not only for industries but also for human life support[1]. Robotic technologies have been cultivated so far within practical industrial applications as a useful article. It is, however, not always in the case of human life support robots because of the complicated versatility of tasks, users, and environments.

Human life environments are not tailored for robots still less than for their work, and robot work would be so versatile. The situation would be also versatile so as that, for example, working situation would differ from the former ever task to be provoked. It could not be estimated so it is eventful. Above all, it is required that a typical robot user who are unfamiliar robotic technologies is able to operate robots under the complicated situation.

In order to deal with these difficulties, intelligent robot is required to provide an appropriate support for robot users who have to operate robots and to make motion planning. The term "intelligent" here refers to induce the change for the variation. Because it is considered that behavior appropriate for variation embodies a sort of intelligent, and that the root of its is to change oneself for the variation.

The purpose of this study is to develop a systematic methodology for intelligent robot system that takes control of itself to make a support for robot users. As the first approach for the purpose, this study investigates a framework of kinematics process model by means of multi-agents system concept (MAS in short). MAS applications has been published in terms of mobile robots[2] and manipulator control[3]. Despite of the kinematics constraint can not be disregarded, MAS based kinematics process is little discussed for universal robotic systems. This paper presents a framework of kinematics process system based on MAS and the detail design of the agents as well as the kinematics sequence. The possible impact of the improved robotic systems is confirmed through the case study.

2 AGENT BASED KINEMATICS PROCESS MODEL

2.1 Framework of kinematics process model

Multi-linked robots are composed of the parts, such as effectors, links, and prismatic or rotational joints. Especially, a pair of joint and adjacent link is a basis of the description of the kinematics properties [4]. This study considers effectors and the pairs of joint/link as a unit component, as illustrated in Figure 1, and corresponds the kinematics process called agent to the unit components. The kinematics solution process is constructed by assembling the agents in accordance with robot mechanism.

There are two types of agents called Local Kinematics Agent (LKA) and Effect Point Agent (EPA). LKA is in charge of the kinematics process for the pairs of joint and link. LKA calculates the rotation angle corresponding to joints for the deviation between the target and the current position of effector, and transmits the joint motion to other LKA located at the tip side of robots. EPA represents the effector, and it calculates the deviation between the current position of effector and its target point.

As shown in Figure 1, the kinematics solution system is configured by associating with the Input/Output relation between LKAs and EPA, and the result of this, LKA and EPA processes are directed by the closed information flow. The kinematics solution is asymptotically obtained as the robot posture in respect to the effector target position.

The feature of this system is to not define explicitly overall direct kinematics model differ from other component type approach[5]. Overall kinematics solution model or function is not formulated until LKM and EPA is related to the each other. Reconfigurable system can be realized by the addition or the remove of LKA.

2.2 Outline of local kinematics

The block diagram of LKA is illustrated in Figure 2. It represents LKA of the j-th joint from the base. LKM consists of main three parts which are called Local Direct Kinematics process, Local Inverse Kinematics process, and Joint State variables.

The Joint State variables are the data to represent joint condition. They are joint position $\mathbf{p}_j$, joint axis $\mathbf{a}_j$ and joint rotation angle θ_j. These values are initialized according to a preliminary position and posture of robots. The Local Inverse Kinematics calculates the rotation angle to be moved for minimizing the deviation between the current position and the target position of effector. The Local Direct Kinematics process consists of two transform operations and a composition operation. The transform operation transforms the Joint State variables in accordance with other joint motion located at the base side. The composition operation composes the motion of oneself and the synthetic motion composed of the previous joints.

For example, the Joint State variables of joint j are transformed by the synthetic motion $\mathbf{R}_j$ and $\mathbf{L}_j$ which are rotation and translation, respectively. Where the motion of joint j is $\mathbf{R}_j$ and $\mathbf{L}_j$, the synthetic motion ${}^1\mathbf{R}_j$, ${}^1\mathbf{L}_j$ is made by composing the motion ${}^1\mathbf{R}_{j-1}$, ${}^1\mathbf{L}_{j-1}$ and the motion $\mathbf{R}_j$, $\mathbf{L}_j$. The synthetic motion is sent to next LKA, and it is composed one after another towards LKAs located at the tip side. EPA refers to effector and its process is the same as LKA in the composition except for the process to obtain the deviation between the current position and the target position of effector instead of Local Inverse Kinematics process. The current position of effecor and the deviation are sent to all of LKA for invoking the Local Inverse Kinematics process.

2.3 Kinematics solution process

The overall kinematics is executed by the successive approximations of LKA process for the deviation calculated by EPA. The local direct kinematics of LKA transforms value of the Joint State variables based on synthetic motion ${}^1\mathbf{R}_{j-1}$ and ${}^1\mathbf{L}_{j-1}$. These are the synthetic motion from the base to joint j-1, for instance in Figure 3. The Joint State variables, therefore, are correctly transformed and the direct kinematics properties are satisfied for the overall robots.

In the j-1degrees of freedom robots, EPA located at j-th from the base transforms the Effector State variables by ${}^1\mathbf{R}_{j-1}$ and ${}^1\mathbf{L}_{j-1}$. The effector position $\mathbf{P}_E$ and the deviation $\Delta\mathbf{P}_G$ sent from EPA to each of LKA and the rotation angle is calculated to minimize the deviation by LKA. The rotation angle accumulates as the joint angle θ_j. When the above processing is repeated at proper times, $\Delta\mathbf{P}_G$ is converged on zero and θ_j is converged on a solution of inverse kinematics problem for the target position $\mathbf{P}_G$.

${}^1\mathbf{R}_{j-1}$, ${}^1\mathbf{L}_{j-1}$, $\mathbf{P}_E$ and $\Delta\mathbf{P}_G$ are obtained from the base side LKA and EPA. Then, ${}^1\mathbf{R}_j$ and ${}^1\mathbf{L}_j$ can be determined from only the Joint State variables Therefore, the direct kinematics can be distributed by LKA. LKA is the same process for all joints. The kinematics process can be composed by attaching or detaching LKA in accordance with the structure of robots and by preliminary Joint State variables.

3 LOCAL KINEMATICS CALCULATION

3.1 Local inverse kinematics

The Local Inverse Kinematics process calculates the deviation angle to minimize the distance between effector and target position. The deviation angle can be represented by the magnitude of vector which is obtained as a joint axis projection of the deviation angle vector. As shown in Figure 4, the deviation angle vector is a plane angle formed between $\mathbf{g}_j$ and $\mathbf{e}_j$. The deviation angle $\Delta\theta_j$ is expressed in the following equation (1).

$$\Delta\theta_j = \begin{cases} 0 & |\mathbf{e}_j \times \mathbf{g}_j| = 0 \\ \mathbf{B}\cdot\mathbf{a}_j \cos^{-1}C & |\mathbf{e}_j \times \mathbf{g}_j| \neq 0 \end{cases} \qquad (1)$$

$$\mathbf{B} = \frac{\mathbf{e}_j \times \mathbf{g}_j}{|\mathbf{e}_j \times \mathbf{g}_j|}, \qquad C = \frac{\mathbf{e}_j \cdot \mathbf{g}_j}{|\mathbf{e}_j|\cdot|\mathbf{g}_j|}$$

$$\mathbf{e}_j = \mathbf{P}_E - \mathbf{p}_j, \qquad \mathbf{g}_j = \mathbf{e}_j + \Delta\mathbf{P}_G$$

Here, $\mathbf{P}_E$ and $\Delta\mathbf{P}_G$ are the information provided from EPA. Also, $\mathbf{e}_j=\mathbf{0}$ and $\mathbf{g}_j=\mathbf{0}$ give singular points of the equation (1), but it is the case of $\mathbf{P}_E+\Delta\mathbf{P}_G=\mathbf{P}_j$ or $\mathbf{P}_E=\mathbf{p}_j$, hence singularity is not noticed in a practical range. Effector motion is a superposition of each joint motion. $\Delta\theta_j$ is approximate value, so, an appropriate proportional constant $K_j(<1)$ is introduced, finally the deviation angle is calculated as $K_j\Delta\theta_j$.

3.2 Local direct kinematics

The local direct kinematics transforms the Joint State variables of LKA in accordance with the synthetic motion sent from the base side LKA. Here, ${}^1\mathbf{R}_{j-1}$ and ${}^1\mathbf{L}_{j-1}$ represent the synthetic motion composed from the base through to the joint j-1. The joint j transforms own Joint State variables by the motion. When the joint position is $\mathbf{P}_j$ and the joint axis is $\mathbf{a}_j$ before transformation, by the motion of ${}^1\mathbf{R}_{j-1}$ and ${}^1\mathbf{L}_{j-1}$, the Joint State variables are transformed as follows.

$$\begin{cases} \tilde{\mathbf{p}}_j = {}^1\mathbf{R}_{j-1}\mathbf{p}_j + {}^1\mathbf{L}_{j-1} \\ \tilde{\mathbf{a}}_j = {}^1\mathbf{R}_{j-1}\mathbf{a}_j \end{cases} \qquad (2)$$

After transformation, for new position $\tilde{\mathbf{p}}_j$ and axis $\tilde{\mathbf{a}}_j$, the rotation $\mathbf{R}_j$ represents as follow from Rodriguez equation when the joint j rotates $\Delta\theta_j$.

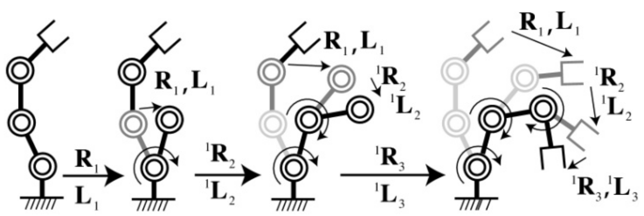

Fig. 3 Direct kinematics calculating process

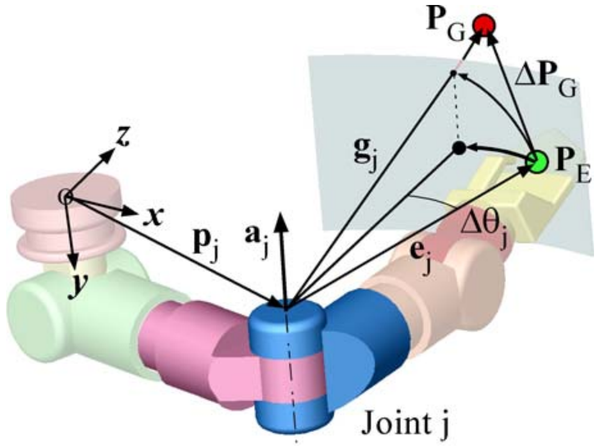

Fig. 4 Schematic of the local inverse kinematics

$$\mathbf{R}_j = \mathbf{E} + [\tilde{\mathbf{a}}_j\times]\sin\Delta\theta_j + [\tilde{\mathbf{a}}_j\times]^2(1-\cos\Delta\theta_j) \qquad (3)$$

Where, $\mathbf{E}$ is a unit matrix, $[\tilde{\mathbf{a}}_j\times]$ is an alternating matrix which is satisfied $\tilde{\mathbf{a}}_j \times \mathbf{p} = [\tilde{\mathbf{a}}_j\times]\mathbf{p}$ with an arbitrary vector $\mathbf{p}$. As shown in Figure 4, $\tilde{\mathbf{a}}_j$ is an axis of rotation passing through $\tilde{\mathbf{p}}_j$. The rotation generated by the joint j with angle $\Delta\theta_j$ transforms an arbitrary point $\mathbf{p}$ and axis $\mathbf{a}$ as follows.

$$\begin{cases} \tilde{\mathbf{p}}_j = \mathbf{R}_j(\mathbf{p}-\tilde{\mathbf{P}}_j) + \tilde{\mathbf{P}}_j = \mathbf{R}_j\mathbf{P} + (\mathbf{E}-\mathbf{R}_j)\tilde{\mathbf{P}}_j \\ \tilde{\mathbf{a}} = \mathbf{R}_j\mathbf{a} \end{cases} \qquad (4)$$

The transformation of $\mathbf{p}$ at equation (4) can be performed by only rotation $\mathbf{R}_j$ around the origin and translation $(\mathbf{E}-\mathbf{R}_j)\tilde{\mathbf{P}}_j$. Consequently, the motion ${}^1\mathbf{R}_j$ and ${}^1\mathbf{L}_j$ which are the composition of $\mathbf{R}_j$, $(\mathbf{E}-\mathbf{R}_j)\tilde{\mathbf{P}}_j$ and ${}^1\mathbf{R}_{j-1}$ and ${}^1\mathbf{L}_{j-1}$ is as follows.

$$\begin{cases} {}^1\mathbf{R}_j = \mathbf{R}_j\,{}^1\mathbf{R}_{j-1} \\ {}^1\mathbf{L}_j = \mathbf{R}_j\,{}^1\mathbf{L}_{j-1} + (\mathbf{E}-\mathbf{R}_j)\tilde{\mathbf{P}}_j \end{cases} \qquad (5)$$

From equation (3) and (4), $\mathbf{R}_j$ and $(\mathbf{E}-\mathbf{R}_j)\tilde{\mathbf{P}}_j$ are determined by only Joint State variables. As ${}^1\mathbf{R}_{j-1}$ and ${}^1\mathbf{L}_{j-1}$ are received from LKA located at the base side, highly independent MAS based kinematics process is available.

4 CASE STUDY

Kinematics solution of 7 d.o.f manipulator

To investigate the proposed framework, the inverse kinematics problem of 7 d.o.f manipulator is executed as illustrated in Figure 5. The initial Joint State variables are show in Figure 5. All of joint angles are set zero at the initial posture, and the end effector is placed on the position (400, 400, 0).

For each iteration by direct and inverse kinematics, the transition of each joint angle is shown in Figure 6. Firstly, some of joint angles had a large value, then these gradually converged a steady value. The transition of position error from the target position is shown in Figure 7. The position error gradually becomes small, after 23 times of iteration processes it is less than 1 mm.

5 CONCLUSION

This paper has presented the framework of kinematics resolution system based on MAS concept and the detail design of the agents as well as the kinematics computation sequence of the system. The feasibility with the possible impact of the improved robot systems has been confirmed through the case study. Conclusions are as follows.

1) Considering a module constructed from joint and link component of robot, defining the Local Kinematics Module (LKA) related to the component and the Effect Point Module (EPA) related to end effector, and the configuration method of a decentralized kinematics calculation model composed of LKA and EPA has proposed.

2) Implementability of decentralizing the calculation of LKA and EPA with respect to each module and calculating the direct and inverse kinematics of manipulator by iterative calculation has been shown.

3) The proposed method has been applied to the inverse kinematics problem of 7 d.o.f manipulator. The computability of the kinematics solution using the proposed calculation model and flexibly with various tasks has been shown.

Abstract: In this study, the optimal processing parameters of polypropylene foam thermoforming are obtained by the use of an artificial neural network. Data from tests carried out on a lab-scale thermoforming machine were used to train an artificial neural network, which serves as an inverse model of the process. The inverse model has the desired product dimensions as inputs and the corresponding processing parameters as outputs. The structure, together with the training methods, of the artificial neural network is also investigated. The feasibility of the proposed method is demonstrated by experimental manufacturing of cups with optimal geometry derived from the finite element method. Except the dimension deviation at one location, which amounts to 17.14 %, deviations of the other locations are all below 3.5 %.

Keywords: Polypropylene Foam, Thermoforming, Artificial Neural Network, Optimal Processing Parameters.

1 INTRODUCTION

Thermoforming has become one of the most important polymer processing methods [1]. However, persistent problems in the selection of processing parameters due to the complex interconnected nature of the involved thermal, chemical, friction and visco-elastic phenomena have confounded the overall success of the process. One of the most serious problems is the lack of an adequate method to derive processing parameters with which prescribed product geometry can be obtained. The parameter-selection problem is of great concern, because it is usually linked with high cost and long start-up time. In practice, the trial-and-error method is relied upon with repeated processing runs to achieve required product geometry. This restriction renders uneconomical a small-batch type manufacturing with accurate product shape.

In this work, an effort was made to develop a technique based on ANN to find a set of thermoforming parameters that will produce foamed plastic products in a prescribed geometry. The technique inverts the relation between processing parameters and product dimensions. The inverse model has the desired product dimensions as inputs and the corresponding processing parameters as outputs. The effects of the design factors of the ANNs on the performance of mapping between product dimensions and processing parameters have also been investigated. Finally, experimental manufacturing of cups was used to test the adequacy of the method developed.

2 ARTIFICIAL NEURAL NETWORKS AND THE BACKPROPAGATION LEARNING RULE

ANN (artificial neural network) is one of the proven general-purpose architectures that are able to generate a nonlinear mapping between two sets of data. In this paper, the inverse model is treated as a mapping between the desired product geometry and the corresponding processing parameters, where the former are inputs and the latter are outputs.

The network architecture used for the inverse model problem is the multilayered feedforward neural network (MFNN)[2]. Figure 1 shows an MFNN with two hidden layers, each layer has a synaptic weight matrix W_i, i = 1, 2, 3, defining the connections between the previous layer and the next layer [3-9]. In Figure 1, the connection between the input patterns and the first hidden layer is defined by the weight matrix $W_1 = [w_{ij}^{(1)}] \in \Re^{N_1 \times N_{in}}$, where N_1 is the number of neurons in the first hidden layer and N_{in} is the number of inputs. The connection between the two hidden layers is defined by the weight matrix $W_2 = [w_{ij}^{(2)}] \in \Re^{N_2 \times N_1}$, where N_2 is the number of neurons in the second hidden layer. The last weight matrix $W_3 = [w_{ij}^{(3)}] \in \Re^{N_3 \times N_2}$ defines the connection between output patterns and the second hidden layer, where N_3 is the dimension of output patterns. Given the network input vector $u \in \Re^{N_{in} \times 1}$, the output of the first hidden layer $X_1 \in \Re^{N_1 \times 1}$, which is the input to the second hidden layer, can be written as

$$X_1 = f_1(W_1 . \; u + B_1)$$

where f_1 ( ) is the nonlinear activation function at each neuron in the first hidden layer and $B_1 \in \Re^{N_1 \times 1}$ is the threshold or bias vector of the same layer. The output of the second hidden layer $X_2 \in \Re^{N_2 \times 1}$ can be written as

$$X_2 = f_2 (W_2 . \; X_1 + B_2)$$

where f_2 ( ) is the nonlinear activation function and B_2 is the bias vector of the second hidden layer. The output of the last layer, which is the response of the network $Y = X_3 \in \Re^{N_3 \times 1}$, can be written as

$$Y = X_3 = f_3(W_3.\ \ X_2 + B_3)$$

where f_3 ( ) is the activation function and B_3 is the bias vector of the output layer.

In the following descriptions, the hidden layers of the ANN under study are composed of neurons with a hyperbolic tangent sigmoid activation function defined as:

$$y = f(v) = \tanh(\alpha v) = \frac{e^{\alpha v} - e^{-\alpha v}}{e^{\alpha v} + e^{-\alpha v}} = \frac{1 - e^{-2\alpha v}}{1 + e^{-2\alpha v}}$$

where the value of α is usually set to be 1. Furthermore, the activation function of the output layer is the linear function. That is,

$$Y = W_3.\ \ X_2 + B_3$$

The backpropagation learning algorithm is the most widely used training process for MFNN with differentiable activation functions today. The algorithm is based on the steepest descent gradient principle aiming at the minimization of deviation between the desired network output and the actual output, defined as the scalar positive function

$$E = \sum_{i=1}^{N_3} (d_i - y_i)^2$$

where d_i represents the desired network output and y_i is the actual output of the MLP corresponding to an input pattern. To emphasize relative deviation, the value of E is further tailored to be in a root of mean squared error form in the subsequent discussion:

$$E_{RMS} = \sqrt{\frac{1}{N_3} \sum_{i=1}^{N_3} (d_i - y_i)^2} \qquad \textbf{(1)}$$

On using the backpropagation algorithm, also called the generalized delta rule, we need to find the local error or delta, $\delta_j^{(s)}$, recursively first:

$$\delta_j^{(s)} = [\sum_{h=1}^{N_{s+1}} \delta_h^{(s+1)} \cdot w_{hj}^{(s+1)}] \cdot g_s(\sum_{i=1}^{N_{s-1}} w_{ji}^{(s)} \cdot x_i^{(s-1)} + b_j^{(s)}) \qquad \textbf{(2)}$$

where s = 1, 2 designates the appropriate network layer, g_s( ) represents the first derivation of the activation function f_s( ) in the s-th layer. And $\delta_j(3)$ for the output layer is evaluated as

$$\delta_j^{(3)} = (d_j - y_j) \cdot g_3(\sum_{h=1}^{N_2} w_{jh}{}^{(3)} x_h^{(2)} + b_j)$$

The learning rule for the weight matrix and bias vector is then given by

$$w_{ji}{}^{(s)}(k+1) = w_{ji}{}^{(s)}(k) + \mu \cdot \delta_j^{(s)} \cdot x_i{}^{(s-1)} \qquad (3)$$

$$b_j^{(s)}(k+1) = b_j^{(s)}(k) + \mu \cdot \delta_j^{(s)} \qquad (4)$$

where k denotes time index, s = 1, 2, 3 designates the appropriate network layer. Furthermore, μ in *Eqs 3* and *4* is the corresponding learning rate parameter, which is an important design factor of an MFNN [2].

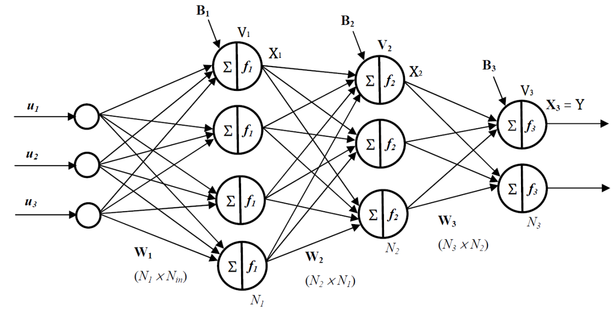

Figure 1. Architecture of a multilayered feedforward neural network (MFNN) with two hidden layers [2].

3 RESULTS AND DISCUSSION

With the network topology and learning rate paramete r being set at optimal values obtained above, Figure 2 shows the convergence history of the RMS prediction error values of the various network outputs. The average training time of a typical run was 12 seconds when executed using a 2.0 GHz Pentium 4 Personal Computer equipped with 1 GB RAM.

We can see that the average RMS error values are all below 0.2. Furthermore, the RMS errors of E and F, that is, the dropping velocity of the assisting plug and the heat transfer coefficient of the assisting plug, can be perfectly reduced below 0.01. We have that the network can fit to the 35 experimental data sets with RMS prediction errors well below 0.02.

Using the training data to assess the network performance can lead to over-fitting. The generalization properties of a neural network cannot be based on the training data alone. Untrained data sets must be used instead to evaluate its generalization capability. We randomly selected 5 experimental data sets, which were not used in the training, as test data sets.

To test the effectiveness of the trained ANN and study fundamental problems associated with inverse model of the thermo forming process, evaluation processes were conducted. The desired cup geometry, which serves as inputs to the ANN, is designed with ANSYS using the Finite Element Method (FEM).

The desired product dimensions were normalized and sent to the trained MFNN to generate outputs. The processing parameters corresponding to the optimal thickness distribution are: A = 187 ^{o}C, B = 91 mm, C = 0.3042 sec, D = 0.02 MPa, E = 222 mm/s, and F = 0.23 W/m·^{o}K (plastic).

Ten cups were manufactured and the average thicknesses of the six sites were obtained. These results are shown graphically in Figure 3. Except the deviation at point 3, which amounts to 17.14 %, dimension deviations of the other points are all below 3.5 % [2].

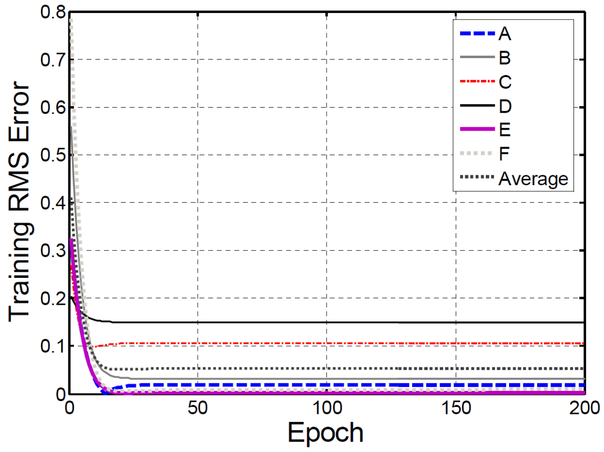

Figure 2. Convergence history of the RMS error values of the training data sets [2].

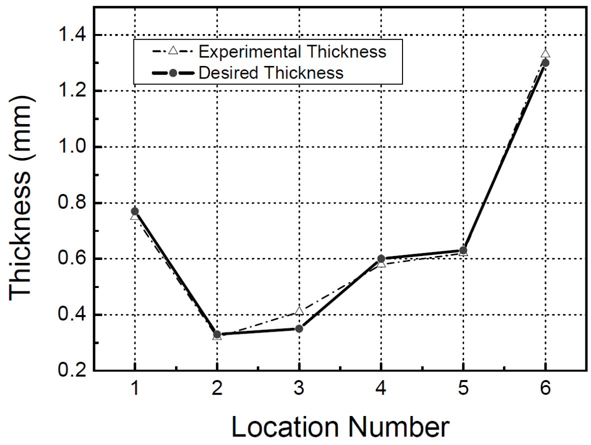

Figure 3. Experimental thickness versus desired thickness [2].

4 CONCLUSION

In this study, inverse model of thermoforming, which is composed of an artificial neural network, has been carried out. Taking thermoforming of the polypropylene foam cups as a specific case, we show in this paper that inverse modeling of a process by a neural network to derive processing parameters is both feasible and practical. This conclusion is justified by experimental results. In addition, inverse model can alleviate the prolonged trial processes required to derive a set of processing parameters corresponding to specified product geometry.

Abstract: Human-beings can prevent crashes by avoiding obstructions when detected it in front of them. At the same time, they can take the best action suitable to the surrounding environment. It is considered that an action control algorithm for a mobile robot is feasible by imitating the above-mentioned action control of human-beings. In this paper, we propose a situational judgment system using a hierarchical neural network. This system outputs the action suitable for a robot to the environment (go straight, go back, turn right, turn left, diagonally forward right, or diagonally forward left). After learning of the system, we mounted the system into the robot and let the robot judge the action in various environments. The experimental results demonstrated that the proposed system was effective for determination of the action of the robot in complex environments.

Keywords: Hierarchical neural network, Robot, Situational judgment

1 INTRODUCTION

Human-beings can prevent crashes by avoiding obstructions when detected it in front of them. At the same time, they can take the best action suitable to the surrounding environment. This is because human-beings can recognize the position and posture of obstructions in relation to those of the person through the use of senses. Therefore it is considered that an action control algorithm for a mobile robot is feasible by imitating the above-mentioned action control of human-beings. In recent year, scientists have been working in research and development of mobile robots with the ability to judge like human-beings'[1].

Until now, we have been developing a situational judgment system that uses a hierarchical neural network(called here, NN)[2, 3]. At first, we developed a situational judgment system that obtains information from a single image(in front of the robot) taken from a CMOS camera mounted in a robot. This process allows the robot to attain 4 correct outputs (go straight, go back, turn right, or turn left) in relation to the environment[4]. However, the situational judgment system could not let the robot judge accurately like a human-beings', because this system only uses one image for input information. We confirmed that the robot mounted this system could not obtain sufficient environmental information from the right side and left side of the robot.

In order to let the robot obtain more environmental information, we have been improving the situational judgment system that obtains information from three images(left side, in front, and right side of the robot) taken from a CMOS camera mounted in a robot[5]. Although the robot was able to obtain more environmental information, outputs of this system were still limited to only 4 outputs. Due to the limitation, the robot was unable to judge similarly to human-beings in complex environments. Accordingly, we confirmed that the improved system was also insufficient as a situational judgment system for a mobile robot.

For this reason, we propose a new situational judgment system with an increase of two extra actions for outputs (diagonally forward right, and diagonally forward left). This proposed system uses a hierarchical NN, and outputs the suitable action to the environment (go straight, go back, turn right, turn left, diagonally forward right, or diagonally forward left). In this paper, we show that the proposed system is effective for determination of the action of the robot in complex environments.

2 SITUATIONAL JUDGMENT SYSTEM

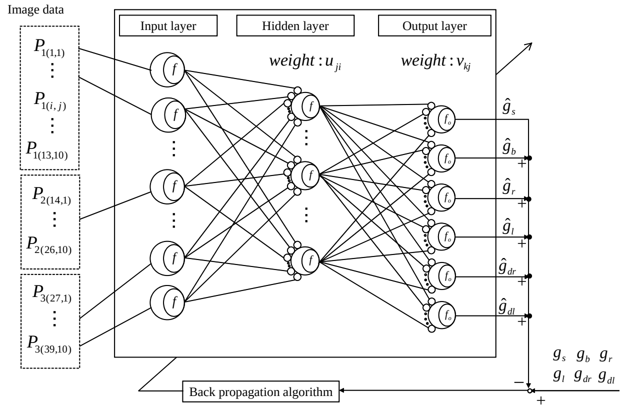

Fig. 1. Situational judgement system

Figure 1 shows the configuration of the proposed situational judgment system using a hierarchical NN. This system inputs images $P_x(i,j)$ that are taken from a CMOS camera mounted in a robot, and outputs the action suitable to the environment (go straight $\hat{g_s}$, go back $\hat{g_b}$, turn right $\hat{g_r}$, turn left $\hat{g_l}$, diagonally forward right $\hat{g_{dr}}$, or diagonally forward left $\hat{g_{dl}}$). Where x is the number of images, i is the number of pixel widths, j is the number of pixel heights.

The NN of the proposed system consists of three layers: input layer, 390 neurons; hidden layer, 195 neurons; and output layer, 6 neurons. In addition, the sigmoid function is used for the nonlinear function of each neuron. Connection weights of the NN are adjusted using a back-propagation algorithm, which is the typical learning technique, so that the sum of square error given by

$$E = \frac{1}{2}\sum\Big\{(g_s-\hat{g_s})^2+(g_b-\hat{g_b})^2+(g_r-\hat{g_r})^2 +(g_l-\hat{g_l})^2+(g_{dr}-\hat{g_{dr}})^2+(g_{dl}-\hat{g_{dl}})^2\Big\} \quad (1)$$

decreases, where g_s, g_b, g_r, g_l, g_{dr}, g_{dl} are the teaching data.

3 IMAGE PROCESSING

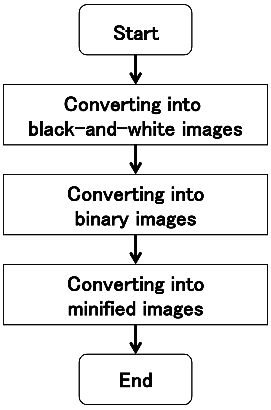

Fig. 2. Flow chart of the image processing

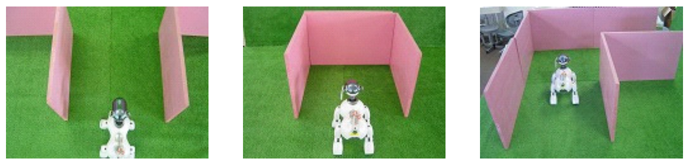
If the amount of input information for the proposed situational judgment system is too much, then the running process of the system will take a lot of time and the proposed situational judgment system will not be able to let a robot judge quickly. Therefore, we use an image processing method to reduce the amount of input information. The proposed situational judgment system inputs processed images by three-step image processing. Figure 2 shows a flow chart of the three-step image processing. At first, the system converts the shot images (colored, 104 pixel widths, and 80 pixel heights) into black-and-white images. Then, the system converts the black-and-white images into binary images. Finally, the system converts the binary images into minified images(13 pixel widths, and 10 pixel heights). These processed images are used to input information for the proposed situational judgment system.

4 LEARNING RESULT

4.1 NN learning

First, we put a robot in environments like Figure 3 and took 108 images of three different directions (6 images each of 6 action patterns) with a camera mounted in the robot. The field of vision of the robot was set to 120 angular degrees for this experiment. These images were used as teaching data, and the proposed situational judgment system was learned. Figure 4 shows some of the images that are used as teaching data.

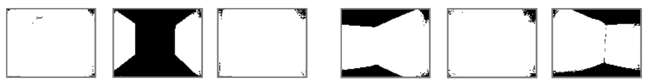
Figure 5 shows the transition of the sum of square error. After two million iterations, the sum of square error decreased and converged to a constant value of about 0.007.



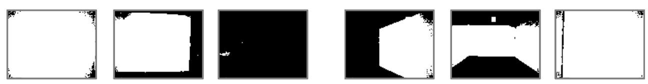
(a) go straight (b) go back (c) turn right

(d) turn left (e) diagonally forward right (f) diagonally forward left

Fig. 3. Example of environments for the NN learning



(a) go straight (b) go back



(c) turn right (d) turn left

(e) diagonally forward right (f) diagonally forward left

Fig. 4. Example of images used for the NN learning

4.2 Simulation result

To confirm the reliability of the NN learning results, we carried out simulation experiment by images used as the

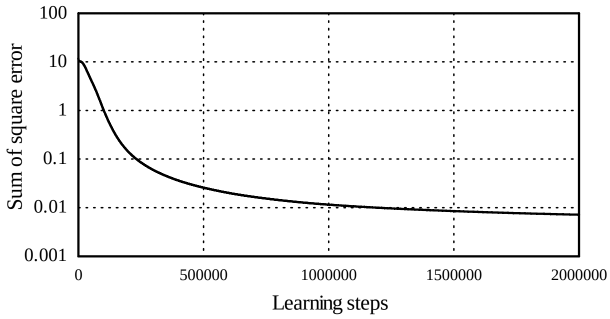


Fig. 5. Transition of the sum of square error

teaching data for the NN learning. Table 1 shows the results of the situational judgment for the simulation experiment. Here, the proposed situational judgment system outputs 6 values from 0 to 1, and the largest value is the best action suitable in each environment. The data values shown in table 1 demonstrate suitable output values for each environment. From these simulation results, we confirmed that the proposed situational judgment system was sufficiently learned.

5 EXPERIMENTAL RESULT IN COMPLEX ENVIRONMENTS

To confirm the usefulness of the proposed situational judgment system, we carried out to let the robot judge the action in complex environments using the learned situational judgment system. The robot mounted the learned system is set in complex environments. Situational judgment results from the robot are displayed on a computer screen using a wireless local area network mounted into the robot as shown in Figure 6. It is important to note that the complex environments are not used as the teaching data for the NN learning.

5.1 Y-junction environment

First, we put the robot in a Y-junction environment shown in Figure 7(a), and let the robot judge the action. Figure 7(b) shows the images shot by the robot in this environment, and

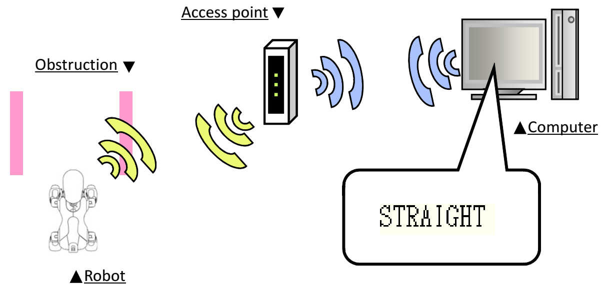

Fig. 6. Experiment system

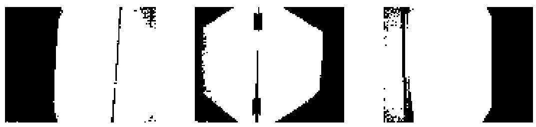
Figure 7(c) shows the images after the previously-mentioned image processing. Table 2 shows the result of the situational judgment obtained from the robot in this environment.

(a) experimental environment

(b) shot images



(c) binary images

Fig. 7. Y-junction environment

Table 1. Results of the situational judgment for the simulation experiment

		Result					
		Straight	Back	Right	Left	D-right	D-left
Input image	Straight	**1.000**	0.016	0.004	0.006	0.008	0.010
	Back	0.011	**0.967**	0.000	0.000	0.000	0.012
	Right	0.003	0.006	**0.982**	0.002	0.000	0.002
	Left	0.001	0.000	0.000	**0.973**	0.003	0.013
	D-right	0.000	0.015	0.006	0.001	**0.998**	0.011
	D-left	0.000	0.010	0.000	0.007	0.016	**1.000**

As can be noted from Table 2, the proposed situational judgment system outputted 2 actions(diagonally forward right, and diagonally forward left) suitable to the Y-junction environment. These results clearly demonstrate that this system can output the accurate action in the complex environment.

Table 2. Results of the situational judgment for the Y-juntion environment

	Straight	Back	Right	Left	D-right	D-left
Output	0.000	0.002	0.003	0.001	**0.997**	**0.986**

5.2 Cross road environment

Next, we put the robot in a cross road environment shown in Figure 8(a), and let the robot judge the action. Figure 8(b) shows the images shot by the robot in this environment, and Figure 8(c) shows the images after the image processing. Table 3 shows the result of the situational judgment obtained from the robot in this environment.

From Table 3, the proposed situational judgment system outputted 3 actions(go straight, turn right and turn left) suitable to the cross road environment. Moreover, we confirmed that the robot can obtain complex environment information by the proposed situational judgment system.

6 CONCLUSION

In this paper, we proposed a situational judgment system using a hierarchical neural network (NN) for a robot. This system outputs the suitable action for the robot to complex environments. The connection weights of the NN are adjusted by the back-propagation algorithm so that the sum of square error decreases to a small value.

To confirm the usefulness of the proposed situational judgment system, we carried out some experiments in complex environments which were not used as the teaching data for the NN learning. From the experiment results, we confirmed that the robot mounted the proposed situational judgment system could output the action similar to a human-beings.

In future works, we plan to construct a running control system for the robot using the proposed situational judgment system. We will target to let the robot run in more complex situations like labyrinth.

Abstract: In this study, a revised Group Method of Data Handling (GMDH)-type neural network self-selecting optimum neuron architectures is applied to the computer aided image diagnosis (CAD) of lung cancer. The GMDH-type neural network algorithm has an ability of self-selecting optimum neural network architecture from three neural network architectures such as sigmoid function neural network, radial basis function (RBF) neural network and polynomial neural network. The GMDH-type neural network also has abilities of self-selecting the number of layers, the number of neurons in hidden layers and useful input variables. This algorithm is applied to CAD and it is shown that this algorithm is useful for CAD of lung cancer and is very easy to apply practical complex problem because optimum neural network architecture is automatically organized.
Keywords: Neural networks, GMDH, Medical image diagnosis.

1. INTRODUCTION

Group Method of Data Handling (GMDH)-type neural networks and their applications have been proposed in our early works [1],[2]. GMDH-type neural networks can automatically organize neural network architecture by heuristic self-organization method [3],[4], which is a kind of evolutional computation, and they can also determine automatically such structural parameters as the number of layers, the number of neurons in hidden layers and useful input variables.

In this study, a revised GMDH-type neural network algorithm self-selecting optimum neural network architecture is applied to the computer aided image diagnosis (CAD) of lung cancer. In this algorithm, optimum neural network architecture is automatically selected from three neural network architectures such as sigmoid function neural network, RBF neural network and polynomial neural network. Furthermore, structural parameters such as the number of layers, the number of neurons in hidden layers and useful input variables are automatically selected so as to minimize prediction error criterion defined as Akaike's information criterion (AIC) [5] or Prediction Sum of Squares (PSS) [6]. The GMDH-type neural network algorithm is applied to CAD of lung cancer and results show that the revised GMDH-type neural network algorithm is useful for CAD of lung cancer and is very easy to apply practical complex problem because optimum neural network architecture is automatically organized.

2. MULTI-LAYERED GMDH-TYPE NEURAL NETWORK SELF-SELECTING FUNCTION

Revised GMDH-type neural network has a common feedforward multilayered architecture. Figure 1 shows architecture of revised GMDH-type neural network.

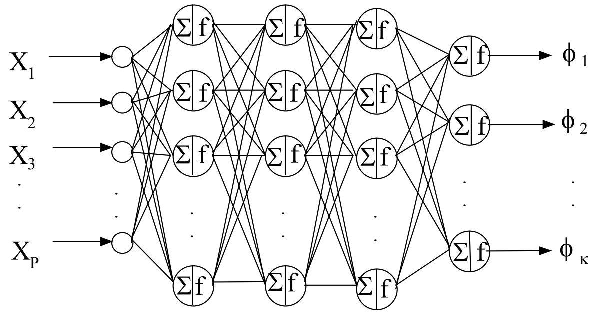

Fig.1 Architecture of revised GMDH-type neural network

2.1 The first layer

$$u_j = x_j \qquad (j=1,2,\ldots,p) \tag{1}$$

where x_j (j=1,2,…,p) are input variables of the nonlinear system, and p is the number of input variables. In the first layer, input variables are set to output variables.

2.2 The second layer

All combinations of r input variables are generated. For each combination, optimum neuron architectures are automatically selected so as to minimize AIC or PSS.

Revised GMDH-type neural network algorithm can select optimum neural network architecture from three neural network architectures such as sigmoid function neural network, RBF neural network and polynomial neural network.

Neuron architectures in each neural network architecture are shown as follows. Neurons are constructed using the first and the second type neuron architectures.

(1) *Sigmoid function neural network*

1) The first type neuron

Σ: (Nonlinear function)

$$z_k=w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3-w_0\theta_1 \quad (2)$$

f : (Nonlinear function)

$$y_k=\frac{1}{1+e^{(-z_k)}} \quad (3)$$

2) The second type neuron

Σ: (Linear function)

$$z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r-w_0\theta_1 \quad (r<p) \quad (4)$$

f : (Nonlinear function)

$$y_k=\frac{1}{1+e^{(-z_k)}} \quad (5)$$

(2) *Radial basis function neural network*

1) The first type neuron

Σ: (Nonlinear function)

$$z_k=w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3-w_0\theta_1 \quad (6)$$

f : (Nonlinear function)

$$y_k=e^{(-z_k^2)} \quad (7)$$

2) The second type neuron

Σ: (Linear function)

$$z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r-w_0\theta_1 \quad (r<p) \quad (8)$$

f : (Nonlinear function)

$$y_k=e^{(-z_k^2)} \quad (9)$$

(3) *Polynomial neural network*

1) The first type neuron

Σ: (Nonlinear function)

$$z_k=w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3-w_0\theta_1 \quad (10)$$

f : (Linear function)

$$y_k=z_k \quad (11)$$

2) The second type neuron

Σ: (Linear function)

$$z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r-w_0\theta_1 \quad (r<p) \quad (12)$$

f : (Linear function)

$$y_k=z_k \quad (13)$$

Here, $\theta_1=1$ and w_i (i=0,1,2,…,9) and w_i (i=0,1,2,…,r) are weights between the first and second layer. Value of r, which is the number of input variables u in each neuron, is set to two for the first type neuron and set to be greater than two and smaller than p for the second type neuron. p is the number of input variables x_i (i=1,2,…,p). Weights w_i (i=0,1,2,…) in each neural network architecture are estimated by stepwise regression analysis [7] using PSS.

[Estimation procedure of weight w_i]

First, values of z_k^{**} are calculated for each neural network architecture as follows.

a)Sigmoid function neural network

$$z_k^{**}=\log_e\left(\frac{\phi'}{1-\phi'}\right) \quad (14)$$

b)RBF neural network

$$z_k^{**}=\sqrt{-\log_e\phi'} \quad (15)$$

c)Polynomial neural network

$$z_k^{**}=\phi \quad (16)$$

where ϕ' is the normalized output variable whose values are between 0 and 1.

Then weights w_i are estimated by stepwise regression analysis [7] which selects useful input variables using AIC or PSS. Only useful variables in Eq.(2), Eq.(4), Eq.(6), Eq.(8), Eq.(10) and Eq.(12) are selected by stepwise regression analysis using AIC or PSS and optimum neuron architectures are organized by selected useful variables.

For each combination, three neuron architectures, which are sigmoid function neuron, RBF neuron and polynomial neuron, are generated and L neurons which minimize PSS are selected for each neuron architecture. From these L selected neurons for each neuron architecture, estimation errors of L neurons are calculated. Then, neural network architecture which has minimum estimation error is selected as revised GMDH-type neural network architecture from three neural network architectures.

After the type of revised GMDH-type neural network architecture is selected, output variables y_k of L selected neurons are set to input variables of neurons in the third layer.

2.3 The third and successive layers

In the second layer, optimum neural network architecture is selected from three neural network architectures. In the third and successive layers, only one neuron architecture, which is sigmoid function neuron or RBF neuron or polynomial neuron, is used for calculation and the same calculation of the second layer is iterated until AIC or PSS values of L neurons with selected neuron architecture stop decreasing. When iterative calculation is terminated, neural network architecture is produced by L selected neurons in each layer.

By using these procedures, the revised GMDH-type neural network self-selecting functions is organized.

3. APPLICATION TO MEDICAL IMAGE DIAGNOSIS OF LUNG CANCER

In this study, the regions of lung cancer were recognized and extracted automatically by using the revised GMDH-type neural network. Multi-detector row CT (MDCT) images of lungs are used in this study. In this application, PSS was used as the prediction error criterion.

3.1 Extraction of candidate image regions of lung cancer.

A lung image shown in Fig. 2 was used for organizing the revised GMDH-type neural network. The statistics of the image densities and x and y coordinates in the neighboring regions, the N×N pixel regions, were used as the image features. Only five parameters namely, mean, standard deviation, variance and x and y coordinates were selected as the useful input variables. The output value of the neural network was zero or one. When N×N pixel region was contained in lung regions, the neural network set the pixel value at the center of the N×N pixel region to one and this pixel was shown as the white point. The neural networks were organized when the values of N were from 3 to 10. It was determined that when N was equal to 4, the neural network architecture had the smallest recognition error. Five useful neurons were selected in each hidden layer. Figure 3 shows the estimation errors of three kinds of neurons in the second layer. The estimation error of the RBF neural network was smallest in three kinds of neurons. The RBF neural network architecture was selected by the revised GMDH-type neural network algorithm. Figure 4 shows the variation of PSS values in the layers. The calculation of the revised GMDH-type neural network was terminated in the eighth layer. The revised GMDH-type neural network outputs the lung image (Fig.5) and the first post-processing analysis of the lung image was carried out. In the first post-processing of the output image, the opening was carried out and small isolated regions were eliminated and the outlines of the lung regions were expanded outside by N/2 pixels. Then, the closing was carried out and the lung regions that did not contain abnormal regions were output. Figure 6 shows the output image after the first post-processing. The output image after the first post-processing was overlapped to the original image (Fig.2) in order to check the accuracy of the image recognition of the lungs as shown in Fig.7. The recognized lung regions are accurate. The lung regions was extracted from the original image using the output image. Figure 8 shows the extracted lung image. The second post-processing such as the opening, closing and so on was carried out in Fig.5 and the lung regions which contained the abnormal regions were obtained as shown in Fig.9. Figure 10 shows the extracted lung image. The candidate image regions of the lung cancer were extracted from Fig.10 using Fig.8 and shown in Fig.11.

3.2 Recognition results of the conventional neural network trained using the back propagation algorithm

A conventional neural network trained using the back propagation algorithm was applied to the same recognition problem and the recognition results were compared with the results obtained using the revised GMDH-type algorithm. The conventional neural network had a three layered architecture and the same five input variables were used in the input layer. The learning calculations of the weights were iterated changing structural parameters such as the number of neurons in the hidden layer and the initial values of the weights. The output images, when the numbers of neurons in the hidden layer (m) are 5, 7 and 9, are shown in Fig.12. These images contain more regions which are not part of the lung and the outlines of the lungs are not extracted with required clarity compared with the output image obtained using the GMDH-type neural network algorithm, which is shown in Fig.5. Note that, in case of the conventional neural network, we obtain many different output images for various structural parameters of the neural network and many iterative calculations of the back propagation are needed for various structural parameters in order to find more accurate neural network architecture.

Fig.12 Output images of conventional sigmoid function neural network

4. CONCLUSION

In this paper, the revised GMDH-type neural network algorithm self-selecting functions was applied to the CAD of lung cancer and the results of the revised GMDH-type neural network were compared with those of the conventional sigmoid function neural network trained using the back propagation algorithm. In this revised GMDH-type neural network algorithm, optimum neural network architecture is automatically selected from three neural network architectures such as sigmoid function neural network, RBF neural network and polynomial neural network. Furthermore, structural parameters such as the number of layers, the number of neurons in hidden layers and useful input variables are automatically selected to minimize prediction error criterion defined as AIC or PSS. In the case of the conventional neural network, we obtain many different output images for various structural parameters of the neural network and many iterative calculations of the back propagation are needed for various structural parameters in order to find more accurate neural network architecture. It was shown that the revised GMDH-type neural network algorithm was a useful method for CAD of lung cancer because the neural network architecture is automatically organized so as to minimize the prediction error criterion defined as AIC or PSS.

Abstract: The support vector machine (SVM) is known as one of the most influential and powerful tools for solving classification and regression problems, but the original SVM does not have an online learning technique. Therefore, many researchers have introduced online learning techniques to the SVM. In a previous article, we proposed an unsupervised online learning method using the technique of the self-organized map for the SVM. In another article, we proposed the midpoint validation method for an improved SVM. We test the performance of the SVM using a combination of the two techniques in this article. In addition, we compare its performance with the original hard margin SVM, and also experiment with our proposed method on surface electromyogram recognition problems with changes in the position of the electrode, and the numerical experiment recognition problem with changes in the time. These experiments showed that our proposed method gave a better performance than the SVM and corresponded to the changing data.

Keywords: Support vector machine, Online learning, Midpoint validation, Pattern classification problem, Surface electromyog ram

1 INTRODUCTION

The support vector machine (SVM) proposed by Cotes and Vapnik is one of the most influential and powerful tools for solving classification problems [1][2][3][4][5].

We studied surface electromyogram (abbr. s-EMG) recognition using the SVM. The purpose was the development of a human interface using an s-EMG. In this study, we considered problems such as the changes in the s-EMG pattern caused by muscle fatigue, and the position of the sensor doing the measurements. In a previous article [6] we proposed the online unsupervised learning method using the technique of a self-organized map for the SVM. Furthermore, the proposed method has a technique for the reconstruction of a SVM.

In addition, we are studying a SVM which is not limited to the recognition of s-EMG. In this study, we pay attention to the problem of the deflection of the separating hyperplane in the input space of a nonlinear SVM, and propose an improved method [7][8]. We call this method the midpoint validation method. This method assumes a midpoint between the classes of training data and an index of the deflection, and moves the separating hyperplane according to the index. This method also has a technique for the reconstruction of a SVM.

These two studies both achieved good results. However, we had not previously combined the two methods. Therefore, we tested the performance of the SVM using a combination of the two techniques. Moreover, we compared its performance with the original hard-margin SVM, Winner Take All model (our previous online method [10]), and also experimented with our proposed method on s-EMG recognition problems with changes in the position of the electrode, and the numerical experiment recognition problem with changes in the time.

2 PROPOSED METHOD

In this section, we introduce the SVM, our online learning method. We also propose a method that combines the online learning method with the midpoint validation method [7][8].

2.1 SVM

A SVM is a mechanical learning system that uses a hypothetical space of linear functions in a high-dimensional feature space. A nonlinear SVM is expressed by Eqs. 1–3. Here, we used the Gaussian kernel given in Eq. 1 as the kernel function, while the SVM decision function g(**x**) and the output of the SVM are as given in Eqs. 2 and 3.

$$K(\mathbf{x},\mathbf{x}_i)=\exp\left(\frac{-\|\mathbf{x}-\mathbf{x}_i\|^2}{2\delta^2}\right) \quad \textbf{(1)}$$

$$g(\mathbf{x})=\sum_{i=1}^{N} w_i K(\mathbf{x},\mathbf{x}_i)+b \quad \textbf{(2)}$$

$$O=sign(g(\mathbf{x})) \quad \textbf{(3)}$$

2.2 Online learning method

In this subsection, we introduce an unsupervised online learning method using the self-organizing map (abbr. SOM) algorithm for the SVM and a restructuring technique.

Let the input space be denoted by $\mathbf{x}_{in} \in$ R. $\mathbf{x}_{in}$ ($in \notin \{i = 1, \ldots, N\}$) is the input vector without the label. The training vectors are included in the kernel function x_i, with $i = 1, \ldots, N$, which belongs to either of the two classes. Therefore, these are given the label $y_i \in \{-1, 1\}$. Each training vector has the same dimensions in input space. The flow of our online learning method is shown in Figs. 1 and 2. The parameter η is an update parameter. The idea of this rule is close to adaptive resonance theory. The parameter s is the Euclidean distance between $\mathbf{x}_{in}$ and each $\mathbf{x}_i$.

Step 1: To find the best mach of the input vector $\mathbf{x}_{in}$ with the training vectors $\mathbf{x}_i$, the Euclidean distance between $\mathbf{x}_{in}$ and each $\mathbf{x}_i$ is computed (Fig. 2a).
Step 2: The following processing (Steps 3-4) are not done to $\mathbf{x}_{in}$ when the label of $\mathbf{x}_{win}$ is not the same as the label of the output result of SVM of $\mathbf{x}_{in}$.
Step 3: To find the best mach of $\mathbf{x}_{win}$ with the training vectors $\mathbf{x}_j$, the Euclidean distance $\mathbf{x}_{win}$, and each $\mathbf{x}_j$ is computed (Fig. 2b).
Step 4: If d_w is condition of the rule of Eq. 4, each $\mathbf{x}_i$ is update according to the learning rule of Eqs. 5 and 6 (Figs. 2c and 2d).
Step 5: Steps 1-4 are done to all input vector.
Step 6: Proposed method repeats *Num* cycles these processing (Steps 1-5) using same inputs vector $\mathbf{x}_{in}$.

$$d_w \leq d_O \qquad (4)$$

$$\mathbf{x}_i^{new} = \mathbf{x}_i^{old} + \eta \cdot f(s)(\mathbf{x}_{in} - \mathbf{x}_i^{old}) \qquad (5)$$

$$f(s) = \begin{cases} \exp(-(3s)^2) \big| y_{win} = y_i & (6.a) \\ 0 \big| y_{win} \neq y_i & (6.b) \end{cases}$$

$$s = \|\mathbf{x}_{in} - \mathbf{x}_i\| \qquad (7)$$

Fig. 1. The flow of the online learning method.

If the SV changes after the update, the SVM is restructured using the updated training vectors. Even if the training vectors change using Steps 1–5, maximizing the margin of the SVM is retained in this restructuring process. In this paper, we first perform the online learning method. Next, we create a SVM with the updated training data. Finally, we perform the midpoint validation method [7][8].

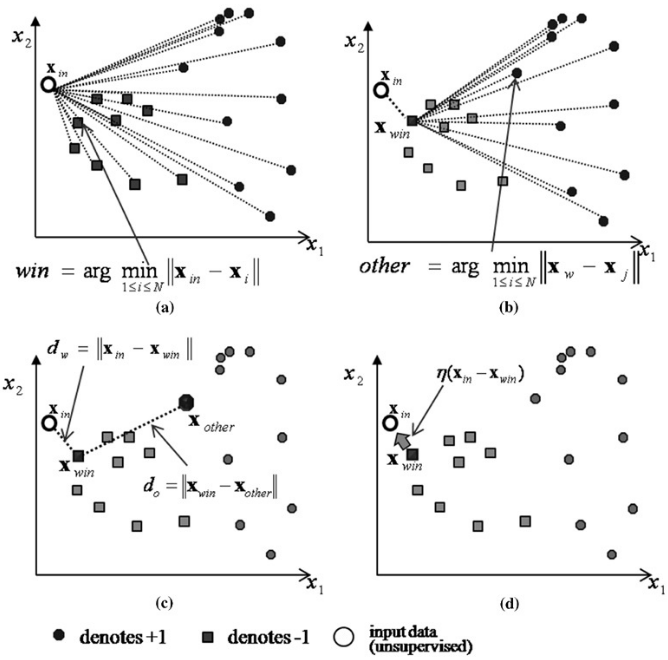

Fig. 2. The flow of the proposed method using SO M. The training vector x_{other} is selected as in (a) and (b). If d_w and d_o are the conditions of the rule in Eq. 4, as in (c), x_{win} is updated using the learning rule in Eq. 5 as in (d).

3 EXPERIMENTS

In this section, the system configuration for experiments on recognizing input data sets changes over time is explained. Next, the system configuration for experiments on recognizing forearm movements using s-EMG is explained. Finally, the results of the computer simulations are described. We compared the performance of the proposed method, Mexican Hat model, Winner Take All (abbr. WTA) model [10], the original hard-margin SVM, and *k*-NN method (form paper [10]). The Mexican Hat model is changed Eq.6.a and b of the proposed method to Eq.8. The WTA model is changed Eq.5 of the proposed method to Eq.9 and not use Eqs.6 and 7.

Mexican Hat model

$$f(s) = \begin{cases} \left(1 - \left(2 \cdot (12s)^2\right)\right) \exp(-(12s)^2) \big| y_{win} = y_i \\ 0 \big| y_{win} \neq y_i \end{cases} \qquad (8)$$

WTA model [10]

$$\mathbf{x}_{win}^{new} = \mathbf{x}_{win}^{old} + \eta \cdot (\mathbf{x}_{in} - \mathbf{x}_{win}^{old}) \qquad (9)$$

3.1 Experimental conditions on numerical

As time-varying input data sets, we created a spiral data sets vary in the two-dimensional space. This is two-class data sets. As class 1, 1000 data were calculated by adding the noise and according to Eqs.10 and 11. As class 2, shifted 180 [deg], 1000 data were created in the same way. In each class, data were divided into training and test data of 900 and 100. In addition, the test data was not chosen from the vicinity of the origin. Shifted 20 [deg] at an angle, 1000 data were created in the same way, in each class. And data were divided into learning and test data of 900 and 100, in each class. Repeat this process 9 times, made 9 data sets.

$$x = 0.1\theta\cos(8\pi\theta) \quad (10)$$

$$y = 0.1\theta\sin(8\pi\theta) \quad (11)$$

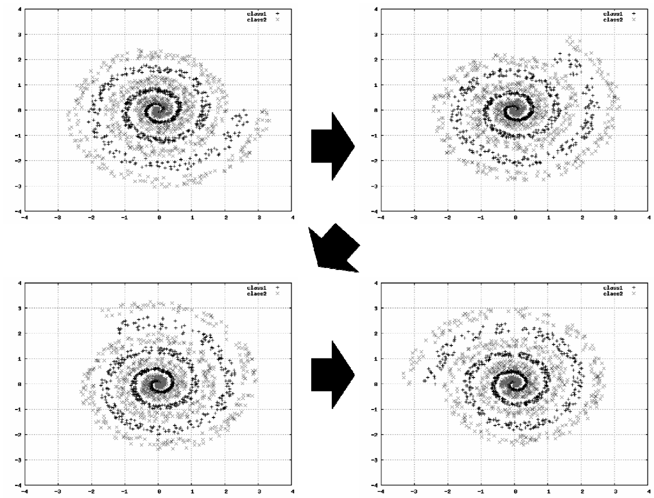

Fig. 3. The spiral data.

3.2 Experiment on numerical

We tested the effectiveness of the proposed method on the spiral recognition problem (Fig.3) that the quantity of the feature changes according to the angle. First, the SVM learn the relation between the coordinate and class from the training data (the training vectors). Next, rotate 20[deg] around the origin. Additional unsupervised learning data (the input vector) are obtained from each class. Last, the recognition rate is calculated from the test data for 100 repeats of each class. The experiments were tested nine times in total by rotating around the origin by 20[deg], 40[deg], 60[deg], 80[deg], 100[deg], 120[deg], 140[deg], 160[deg] and 180[deg]. The basis of the proposed method is the hard-margin SVM using Eq. 1. The Gaussian kernel parameters of the SVM were decided from an evaluation using the training data. Gaussian kernel parameter δ was 0.3. In this experiment, the value of parameter η was 0.1, and the value of *Num* was 1.

3.3 Experimental conditions on forearm muscles

The s-EMG of each movement pattern is measured with electrode sensors, and the quantity of the feature is extracted from the s-EMG. The quantity of the feature is given to the recognition machine as an input, and each movement pattern that generates s-EMG is presumed. The quantity of the feature uses the minimum–maximum values and integration values used by Tamura et al [9]. That article showed that the technique of min–max values and integration values is easier and better than fast Fourier transform processing. The sampling frequency of the measurement data was 1 KHz, and the sampling band was from 0 Hz to 500 Hz.

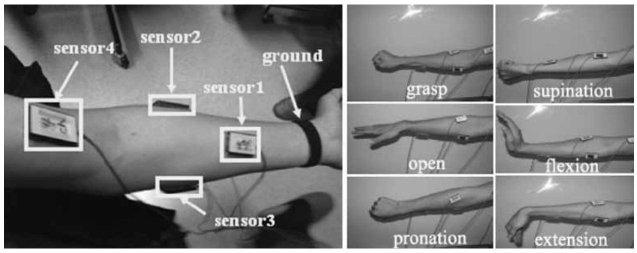

Fig. 4. Image of the forearm motion.

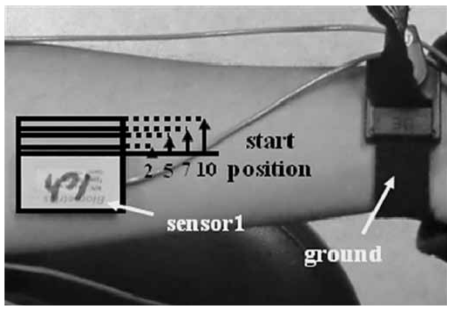

Fig. 5. S-EMG recognition problems with changes in the electrode position (2mm, 5mm, 7mm and 10mm).

3.4 Experiments on forearm muscles

We tested the effectiveness of the proposed method on the s-EMG recognition problem that the quantity of the feature changes according to the position of the electrode. The experimental subjects were three healthy men (T.Y, K.F and S.Y). The subjects sat on a chair. The recognition experiment of the six motion patterns was conducted using s-EMG obtained from four sensors set on the right arm (Fig. 4). Eight inputs were given to the identification machine. The experiments were conducted for 1 day. First, we acquired the training data from the s-EMG concerning the movements of the forearm. Then, the SVM learn the relation between the s-EMG and motion from the training data (the training vectors). Each movement is identified 60 times. Next, the electrode position (sensor 1) is moved 2 mm. Additional unsupervised learning data (the input vector: each motion is repeated 20 or 40 times) are obtained from each movement. Last, the recognition rate is calculated from the test data for 20 repeats of each movement. The measurements were tested four times in total by moving the electrode position by 2 mm, 5 mm, 7 mm, and 10 mm (Fig. 5). The basis of the proposed method is the hard-margin SVM using Eq. 1. The Gaussian kernel parameters of the SVM were decided from an evaluation using the training data. Subject T.Y was 0.7, K.F was 2.0, and S.Y was 0.9. In these experiments, the value of parameter η was 0.1 (on subject T.Y and S.Y) or 0.05 (on subject K.F), and the value of *Num* was 1.

3.5 Experimental result

The results for each simulation method are given in table 1 and 2. In table 1, we show the average success rate of experiment without midpoint validation. From table 1, the proposed method is better than WTA model on result of numeric and subject T.Y. However, Mexican Hat model is worse than the original SVM. Therefore, we consider three methods except the Mexican Hat model. In table 2, we show the average success rate of experiment with midpoint validation. From table 2, the proposed method is better than WTA model on result of numeric and subject T.Y. But, the proposed method is not effective on the subject S.Y. From these results, WTA model had better results, and the proposed method has specialty data and non-specialty data.

Table 1. Average success rate (%) of experiment without Midpoint validation method.

	Numerical	s-EMG		
		T.Y	K.F	S.Y
WTA model	56.3	80.0	**83.3**	**77.7**
Mexican Hat model	53.5	75.8	72.2	59.2
Proposed Method	**66.2**	**85.7**	81.7	72.2
original SVM	50.8	78.5	77.8	76.3

Table 2. Average success rate (%) of experiment with Midpoint validation method.

	Numerical	s-EMG		
		T.Y	K.F	S.Y
WTA model	54.6	81.7	**84.2**	**86.7**
Proposed Method	**68.1**	**86.3**	81.3	70.8
SVM+MV	48.1	77.0	80.8	81.3
k-NN method	-	80.8	82.1	77.7

4 CONCLUSIONS

In this paper, we have proposed a technique of the online learning method using SOM algorithm for nonlinear SVM. The experimental results show that the proposed method is effective in the data which changes uniformly like numerical problem. WTA model is effective in the data which changes irregularly. WTA model is suitable for the recognition problems of s-EMG, because to change irregularly in many cases. The merit of our proposed online method is that the proposed method can be used effectively by setting only one parameter η. The parameter η may be around 0.1. Therefore, the proposed method is useful. In future work, we will experiment on the effectiveness of the proposed method in other problems.

Abstract: Financial market forecasting is a challenging problem and researchers are still exploring the ways to improve the performance of the existing models. This paper presents a forecasting model by integrating wavelet transform, K-means clustering with support vector machine. At the first stage, noise of the input prices is removed by using wavelet denoising. Wavelet multiresolution analysis is used to decompose the original time series in to multiple details and approximated decompositions. Individual support vector models are trained for each detail part. Approximated part is further analyzed by clustering and training support vector models for each cluster. Finally the forecast is made for the wavelet denoised time series by summing up the forecasts of each support vector model. Results have shown that the proposed model has given the accurate forecast and has the capability to support decisions in real world trading.

Keywords: Support vector machine, wavelet transform, K-means clustering, financial market forecasting.

1 INTRODUCTION

Financial market forecasting has been drawn considerable attention in recent years. Accurate forecast of currencies, indices and commodities has become an important issue in decision making in investments. Forecasting financial time series have become a difficult task because of its noisy, nonstationary characteristics and dependence on lot of economic, political environmental and even psychological factors. Forecasters are trying to develop various forecasting techniques in order to reduce the risk of trading. Neural network has become a good alternative over traditional methods like Random Walk model, Box-Jenkins ARIMA, Hidden Markov model etc., because of its capabilities in nonlinear data analysis and universal function approximation Yu et al [1].

Various neural models such as feed-forward, recurrent, radial basis, probabilistic and Support vector machine (SVM) have been developed and researchers are still exploring the ways to improve the forecasting performance of the neural models. Among those models, SVM that is a new kind of kernel based learning machine based on statistical learning theory, has become a good alternative over other neural architectures because of its structural risk minimization property.

In Roshan et al [2], data preparing and architecture determination has identified as the two main problems in building a model for financial market forecasting and new modeling directions have been explored. At the first stage, noise of the signal and the correlation of the inputs should be removed. Thereafter most influential inputs should be selected for the model. Clustering should be done on selected input space where the inputs with similar statistical features are grouped together. Individual models should be created for each cluster and final model should be an ensemble of all individual models.

Therefore this study is focused on improving the forecasting capability of SVM by integrating wavelet transform and k-means clustering according to the above mentioned modeling direction. Section 2 describes the theoretical background of the SVM, K-means clustering and wavelet transform. The simulation results and discussion are given in section 3. Finally the collusions are given.

2 THEORETICAL BACKGROUND

2.1 Support vector machine

The support vector machine (SVM) was proposed by Vapnik [3] and it is based on the structured risk minimization principle. SVM minimize the upper bound of the generalization error by automatically by estimating optimal VC-dimension h with its nested architecture Hayking [4]. SVM is first proposed for pattern classification of two classes and further extended to multi class pattern classification and regression analysis. The SVM regression function can be stated as follows

$$t = W^T \emptyset(X) + b \qquad (1)$$

Where $\emptyset(X)$ is the nonlinear mapping-function. W and b can be estimated as follows.

$$R(C) = C\frac{1}{n}\sum_{i=1}^{N} L_\varepsilon(r_i, t_i) + \frac{1}{2}\|W\|^2 \qquad (2)$$

Where,

$$L_\varepsilon(r_i, t_i) = \begin{cases} |r_i - t_i| - \varepsilon, & |r_i - t_i| \geq \varepsilon \\ 0, & else \end{cases} \qquad (3)$$

r_i is the actual price at the ith period and t_i is the model prediction. $L_\varepsilon(r_i, t_i)$ is called ε-intensive loss function. Term $C\frac{1}{n}\sum_{i=1}^{N} L_\varepsilon(r_i, t_i)$ is the empirical error and the term $\frac{1}{2}\|W\|^2$ is the measure of the smoothness. Tradeoff between empirical risk and smoothness is controlled by C.

Issue to be resolved is to minimize the empirical risk. We can reformulate this optimization problem by introducing two sets of nonnegative slack variables ε_i and ε_i^*. Then the Eq.(2) is can be transformed in to following constrained optimization.

$$\min_{W,b,\varepsilon_i,\varepsilon_i^*} R(W,\varepsilon_i,\varepsilon_i^*) = \frac{1}{2}W^TW + C\{\sum_{i=1}^{N}(\varepsilon_i + \varepsilon_i^*)\} \quad (4)$$

Subject to,

$$W^t\emptyset(X_i) + b - r_i \leq \varepsilon + \varepsilon_i^*$$

$$r_i - W^t\emptyset(X_i) - b \leq \varepsilon + \varepsilon_i$$

$$\varepsilon_i, \varepsilon_i^* \geq 0$$

Taking Lagrangian and conditions for optimality, model can be represented in dual as follows.

$$f(X,a,a^*) = \sum_{i=1}^{N}(\alpha_i - \alpha_i^*)K(X,X_i) + b \qquad (5)$$

Where α_i and α_i^* are nonzero Lagrangian multipliers which are the solution the dual problem. $K(X,X_i)$ is the kernel function.

$$K(X,X_i) = exp\left\{-\frac{(X-X_i)^2}{\sigma^2}\right\}$$

Radial basis kernel is utilized in this study with empirically obtained near optimal σ and C

2.2 Wavelet transform

Wavelet transform has proven to be highly effective in analyzing noisy and nonstationary time series by number of researchers. Consider real or complex value continues time function $\psi(t)$ with following characteristics.

1. It is integrable to zero

$$\int_{-\infty}^{\infty} \psi(t)\, dt = 0 \qquad (6)$$

2. It is square integrable (has finite energy)

$$\int_{-\infty}^{\infty} |\psi(t)|^2\, dt < \infty \qquad (7)$$

3. Admissibility condition

$$\int_{-\infty}^{\infty} \frac{|\psi'(w)|^2}{w}\, dw < \infty \qquad (8)$$

Where ψ' is fourier transform of ψ

2.2.1 Continuous wavelet transform (CWT)

If a function $\psi(t)$ fulfill above (6), (7), (8) conditions, then the continues wavelet transform can be defined as follows

$$C(a,b) = \int_{-\infty}^{\infty} f(t)\, \Psi_{a,b}(t) dt \qquad (9)$$

Where $\Psi_{a,b}(t) = e^{1/2}\,\Psi\left(\frac{t-b}{a}\right)$ is the mother wavelet. a is scale parameter and b is a translation parameter. The relationship between scale and frequency is that low scales correspond to high frequencies and high scales correspond to low frequencies. CWT has much redundant information of the time series and also takes lot of computation time. There for discrete wavelet transform (DWT) has been introduced to eliminate these shortcomings.

2.2.2. Discrete wavelet transform

Definition of the discrete wavelet transform can be given as follows.

$$C(a,b) = C(j,k) = 2^{\frac{j}{2}}\psi_{j,k}(n) \qquad (10)$$

Parameters a and b are defined as $a = 2^j, b = 2^jk$

2.2.3 Stationary wavelet transform

Discrete wavelet transform suffers from a drawback of shift variance. That means discrete wavelet transform (DWT) of a signal is differ from the DWT of the shifted version of the same signal due to decimation step involved in the DWT Coifman & Donoho [5]. Stationary wavelet transform is designed by removing decimation step in order to avoid shift variance. It is a necessary property for time series analysis. Therefore Stationary wavelet transform has utilized in this study.

2.3 K-means clustering

In statistics and data mining, K-means clustering is a method of cluster analysis. Importance of the clustering input space is, to remove bias variance dilemma and improve overall generalization. K-means clustering is used to partition n observations into k clusters and each observation belongs to the cluster with the nearest mean. Given a set of observations n with m-dimensional real vector, K-means clustering partitions the n observations into k clusters $(k < n)$ and minimize the sum of squares within-each cluster

$$arg\ min \sum_{i=1}^{k} \sum_{X_j \in S_i} \left\| X_j - \mu_i \right\|^2 \qquad (11)$$

where μ_i is the center of the cluster S_i

3 SIMULATION RESULTS

3.1 Forecasting model

In the simulation, model was tested for an actual market condition where new data comes in at every step. In this situation, model has no information what so ever about the next step value. Number of researchers in previous studies has performed financial time series forecasting without taking actual market conditions into consideration. This has led to better testing results but doesn't have capability to make profit in real market conditions

Input selection for financial forecasting often takes a critical place because of the accuracy of the output is entirely depends on the characteristics of inputs. Therefore three types of inputs: time delay price values, simple moving average and exponential moving average, have checked upon the performance of the model. Two moving averages ranges (7 min and 30 min) were tested in the comparison.

Proposed model combines SVM regression, Wavelet decomposition and K-means clustering. Input data is scaled up to reduce the mean squared error of the model. Noise of the input data is further removed by using wavelet denoising, which can be achieved by removing small wavelet coefficients in wavelet decomposition by applying appropriate threshold value, even though averaging methods such as moving averages reduces some amount of noise from the data. Then the approximation and detail parts of the time series have reconstructed separately. Individual SVM models with radial basis kernel and debauchee's wavelet is used for each detailed part.

Radial basis kernel which maps inputs in to an infinite dimensional feature space, has selected according to the Cover's theorem of data mapping Cover [6]. Approximation part is further analyzed by using K-means clustering. Bias variance dilemma is expected to be removed by clustering according to principle of divide and conquer Hayking [7]. Multiple clusters have been created for approximation part of the signal by using K-means clustering. Separate SVM model has created for each cluster. New input vector was assigned to a cluster that has minimum distance from its center and the forecast is made by SVM related to the cluster. Then the output is taken by summing up all SVM models that has been created for detail and approximation parts.

Stationary wavelet transform is highly effective in above steps because of its capabilities in time and frequency localization, orthogonal data mapping and ability to fully reconstruct the original time series. Finally one step ahead and multistep ahead forecast has performed and results were compared with pure SVM regression model and wavelet-SVM regression model.

Pure SVM model has the originally proposed architecture with optimally selected parameters while Wavelet-SVM regression model first decompose original time series in to multiple decompositions and each composition is forecasted using separate SVM regression model and finally results were summed up over all decompositions. Directional statistics (D_stat) and mean squared error (MSE) have used as the performance measures. Model is checked for EUR/USD currency pair which is known to be the most volatile of them all. 1 min values have taken in to the forecast. When removing the noise, 1 min data has the advantage of allowing considerable amount of noise reduction without affecting the profit taking opportunities.

3.2. Results

3.2.1 Pure SVM performance

The results of one step ahead forecast is given in Table 1 and has shown the forecast of pure SVM model is capable of forecasting EUR/USD with great accuracy. But it is only with moving average inputs. Result of the pure SVM is the worst of three models for direct input of time delay data. Even though wavelet denoising has improved the directional performance measure for time series data, it can be clearly seen that wavelet denoising has reduced the accuracy of directional forecast. This is due to the fact that the last few values of the denoised time series are chaotic due to real market conditions. Wavelet transform cannot remove the noise of the values at the edge of the time series. Forecast should be done with those values at every step. Therefore noisy wavelet values at the edge have misled the accuracy of the forecast.

SVM-wavelet model has performed better than pure SVM only when the inputs are past time series data. Again the forecast with moving average inputs is further derogated by wavelet decomposition and wavelet noise reduction. Integration of wavelet transform further increased the error due to the above-mentioned reason.

3.2.2 Importance of the multistep ahead forecast

Even though pure SVM model has shown great accuracy in one step ahead forecasting of moving averages, one step ahead forecasting of moving average data cannot directly used to trade in real markets. It is because of the lag which is an undesirable property of moving average indicators. Therefore one-step forecast accuracy of moving average indicators has no use in real trading systems. However, if the moving average is shifted backwards, the lag will be removed and the cost for removing lag will be a multistep ahead forecast. Chaotic values of the edge of the wavelet coefficients can also be removed by going through same procedure. Again multistep ahead forecast will be needed in order to eliminate the lag. Results of the multistep ahead forecast can be directly used for high frequency trading in real financial markets

3.2.3 Result of multistep ahead forecast.

Results given in the Table 2, shows that the proposed model has outperformed both Pure SVM model and wavelet transformed model in both MSE and D_stat in multistep ahead forecast. Table 2 shows the results for 5 step ahead forecast which was the best performed among multistep forecast. Directional accuracy and MSE of the pure SVM has greatly reduced in the multi-step ahead forecast. Elimination of chaotic values of the wavelet decomposition leads to better directional accuracy of SVM-wavelet model with time series data. Even though 30 min moving average has led to better performance of the model, large period of averaging may has the disadvantage of missing sharp peaks. Thus selection of moving average should be optimized along with the profit of the system.

4 CONCLUSION

This study propose a reliable financial forecasting model by integrating wavelet transform k-means clustering and support vector machine. Even though wavelet transform isn't suitable for single step ahead forecast, it can be highly effective with multistep ahead forecast. Proposed model has the ability to forecast multi step ahead values in with great accuracy. Simple moving average with wavelet noise reduction has over performed other two types of input

Table 1. Single step ahead forecast

Model	Time series data		Simple Moving average		Exponential moving average

Abstract: A revised Group Method of Data Handling (GMDH)-type neural network algorithm using knowledge base for medical image diagnosis is proposed and is applied to medical image diagnosis of the liver cancer. In this algorithm, the knowledge base for medical image diagnosis is used for organizing the neural network architecture for medical image diagnosis. Furthermore, the revised GMDH-type neural network algorithm has a feedback loop and can identify the characteristics of the medical images accurately using feedback loop calculations. It is shown that the revised GMDH-type neural network is accurate and a useful method for the medical image diagnosis of the liver cancer.
Keywords: Neural networks, GMDH, Medical image diagnosis, Artificial intelligence.

1. INTRODUCTION

The conventional GMDH-type neural network algorithms were proposed in our early works [1],[2]. In this paper, a revised GMDH-type neural network algorithm using knowledge base is proposed and is applied to the medical image diagnosis of liver cancer. In this revised GMDH-type neural network, the knowledge base for medical image diagnosis is used for organizing the neural network architecture. In the knowledge base system, the various kinds of the knowledge such as the medical knowledge, the image processing knowledge and others, are memorized and these knowledge are used to organize the neural network architecture. Furthermore, the revised GMDH-type neural network algorithm has a feedback loop and can identify the characteristics of the medical images accurately using feedback loop calculations. The neural network architecture is selected from three types of neural network architectures such as the sigmoid function type neural network, the radial basis function (RBF) type neural network and the polynomial type neural network using the knowledge base system. Furthermore, the structural parameters such as the number of feedback loops, the number of neurons in the hidden layers and the relevant input variables are automatically selected using heuristic self-organization method [3],[4], which is a kind of evolutional computation, so as to minimize the prediction error criterion defined as Akaike's information criterion (AIC) or Prediction Sum of Squares (PSS)[5].

2. FEEDBACK GMDH-TYPE NEURAL NETWORK USING KNOWLEDGE BASE

Neural network architecture is shown in Fig.1. In this algorithm, the neural network architecture is automatically organized using the knowledge base. The rules in the knowledge base are classified to the following five types.

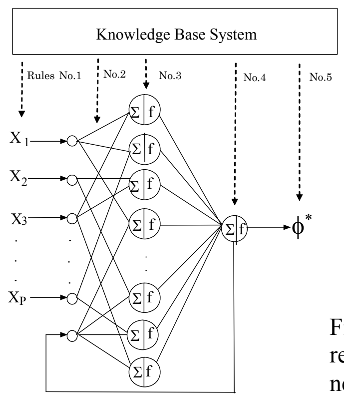

Fig.1 Architecture of revised GMDH-type neural network

2.1 Knowledge base

(1) First type rules.

These rules are concerned with the pre-processing of the original image such as the filtering, the thresh hold processing and so on and the image characteristics of the original image are extracted.

(2) Second type rules.

In the GMDH-type neural network, all combinations of the input variables are generated and the architecture of the neural network is organized using only selected combinations so as to minimize the prediction errors defined as AIC or PSS. In the revised GMDH-type neural network, the combinations of the input variables are controlled using the rules of the knowledge base.

(3) Third type rules.

In the conventional GMDH-type neural network [2], the following seven neuronal architectures are used for organizing neural network to fit the complexity of the nonlinear system. Here, u_i (i =1,2,…,p) and u_j (j =1,2,…,p) show the input variables of the neurons and p is the number of input variables. θ_1=1 and w_i (i=0,1,2,⋯) are weights between the neurons.

1) First type neuron

Σ: (Nonlinear function) $z_k= w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3 - w_0\theta_1$ (1)

f : (Nonlinear function) $y_k= 1 / (1+\exp(-z_k))$ (2)

2) Second type neuron

Σ: (Linear function) $z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r - w_0\theta_1$ ($r<p$) (3)

f : (Nonlinear function) $y_k= 1 / (1+\exp(-z_k))$ (4)

3) Third type neuron

Σ: (Nonlinear function) $z_k= w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3 - w_0\theta_1$ (5)

f : (Nonlinear function) $y_k= \exp(-z_k^2)$ (6)

4) Fourth type neuron

Σ: (Linear function) $z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r - w_0\theta_1$ ($r<p$) (7)

f : (Nonlinear function) $y_k= \exp(-z_k^2)$ (8)

5) Fifth type neuron

Σ: (Nonlinear function) $z_k= w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3 - w_0\theta_1$ (9)

f : (Linear function) $y_k= z_k$ (10)

6) Sixth type neuron

Σ: (Linear function) $z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r - w_0\theta_1$ ($r<p$) (11)

f : (Linear function) $y_k= z_k$ (12)

7) Seventh type neuron

Σ: (Linear function) $z_k= w_1u_1+w_2u_2+w_3u_3+\cdots+w_ru_r - w_0\theta_1$ ($r<p$) (13)

f : (Nonlinear function) $y_k= a_0+a_1z_k+a_2z_k^2+\cdots+a_mz_k^m$ (14)

In the revised GMDH-type neural network, many kinds of the functions can be used as the neuronal architecture and the desirable neuronal architecture in the hidden layer is selected using the third type rules according to the medical or the physical knowledge.

When these rules concerned with the neuronal architecture are not obtained previously, the optimum neuronal architectures fitting the complexity of the nonlinear system are selected automatically so as to minimize the prediction error defined as AIC or PSS.

(4) Fourth type rules.

The neuronal architecture in the output layer is selected using the fourth type rules. When these rules concerned with the neuronal architecture are not obtained previously, the optimum neuronal architectures is selected automatically so as to minimize AIC or PSS.

(5) Fifth type rules.

These rules are concerned with the post-processing of the output images of the neural network. The post-processing such as the closing, the opening and so on are selected using the fifth type rules.

In this paper, we apply the revised GMDH-type neural network to the medical image diagnosis of the liver cancer and the following rules are used in this application.

a) Second type rules.

We do not make the limitations in the combinations of the input variables.

b) Third type rules.

The first type neuronal architecture is used in the hidden layer.

c) Fourth type rules.

The second type neuronal architecture is used in the output layer.

The architecture of the revised GMDH-type neural network is produced concretely using these rules as follows:

2.2 First loop calculation

First, all data are set to the training data. In this study, we used PSS as the prediction error criterion.

(1)Input layer

$u_j=x_j$ (j=1,2,⋯,p) (15)

where x_j (j=1,2,⋯,p) are the input variables of the system, and p is the number of input variables. In the input layer, input variables are set to the output variables.

(2)Hidden layer

All combinations of two variables (u_i,u_j) are generated. For each combination, the neuronal architecture is described by the following equations:

Σ: (Nonlinear function) $z_k= w_1u_i+w_2u_j+w_3u_iu_j+w_4u_i^2+w_5u_j^2+w_6u_i^3+w_7u_i^2u_j+w_8u_iu_j^2+w_9u_j^3 - w_0\theta_1$ (16)

f : (Linear function) $y_k= 1 / (1+\exp(-z_k))$ (17)

where θ_1 =1 and w_i (i=0,1,2,⋯,9) are weights between the input and hidden layer. This neuron is equal to the first type neuron of the conventional GMDH-type neural network. The weights w_i (i=0,1,2,⋯,9) are estimated by using the multiple regression analysis.

This procedure is as follows:

First, the values of z^{**} are calculated by using the following equation:

$$z_k^{**} = \log_e\left(\frac{\phi'}{1-\phi'}\right) \tag{18}$$

where ϕ' is the normalized output variable whose values are between 0 and 1. Then the weights w_i (i=0,1,2,⋯,9) are estimated by using the stepwise regression analysis which selects useful input variables by using the PSS[5].

From these generated neurons, L neurons which minimize the PSS are selected. The output values (y_i) of L

The Seventeenth International Symposium on Artificial Life and Robotics 2012 (AROB 17th '12),
B-Con Plaza, Beppu, Oita, Japan, January 19-21, 2012

selected neurons are set to the input values (u_i) of the neuron in the output layer.

$$u_i = y_i \qquad (i=1,2,\ldots,L) \tag{19}$$

(3)Output layer

The inputs (u_i) of the neuron in the output layer are combined by the following linear function.

$$z = w_0 + \sum_{i=1}^{L} w_i u_i \tag{20}$$

The useful intermediate variables (u_i) are selected by using the stepwise regression analysis in which PSS is used as the variable selection criterion. Then, the estimated output values (z) is used as the feedback value and it is combined with the input variables in the next loop calculation.

2.3 Second and subsequent loop calculations

First, the estimated output value (z) is combined with the input variables and all combinations between the estimated output value (z) and the input variables are generated. The same calculation as the first feedback loop is carried out for each combination. When PSS value of the linear function in (20) does not decrease, the loop calculation is terminated. The output values of the neural network (ϕ^*) are calculated from z as follows:

$$\phi^* = 1 / (1+\exp(-z)) \tag{21}$$

So, in the last feedback loop, the neuronal architecture becomes as follows:

Σ: (Nonlinear function) $\quad z = w_0 + \sum_{i=1}^{L} w_i u_i \quad (22)$

f : (Nonlinear function) $\quad \phi^* = 1 / (1+\exp(-z)) \quad (23)$

This neuron equal to the second type neuron of the conventional GMDH-type neural network.

By using these procedures, the revised GMDH-type neural network can be organized.

3. APPLICATION TO MEDICAL IMAGE DIAGNOSIS OF LIVER CANCER

Multi-detector row CT (MDCT) images of the liver are used in this study.

3.1 Extraction of the candidate image regions of the liver cancer.

A liver image shown in Fig. 2 was used for organizing the revised GMDH-type neural network. By the first type rules, we used the statistics of the image densities and x and y coordinates in the neighboring regions, the $N \times N$ pixel regions, as the image features. As the results, only five parameters namely, mean, standard deviation, variance and x and y coordinates were selected as the useful input variables. The output value of the neural network was zero or one. When $N \times N$ pixel region was contained in the liver region, the neural network set the pixel value at the center of the $N \times N$ pixel region to one and this pixel was shown as the white point. The neural networks were organized when the values of N were from 3 to 10. It was determined that when N was equal to 5, the neural network architecture had the smallest recognition error. Five useful neurons were selected in each hidden layer. Figure 3 shows the variation of PSS values in the layers. The calculation of the revised GMDH-type neural network was terminated in the eighth feedback loop. The PSS value in the first feedback loop was not small but the PSS value was decreased gradually through the feedback loops and the small PSS vale was obtained in the eighth feedback loop. The revised GMDH-type neural network outputs the liver image (Fig.4) and the first post-processing analysis of the liver image was carried out using the fifth type rules. In the first post-processing of the output image, the small isolated regions were eliminated and the outlines of the liver regions were expanded outside by N/2 pixels. Figure 5 shows the output image after the first post-processing. The output image after the first post-processing was overlapped to the original image (Fig.2) in order to check the accuracy of the image recognition as shown in Fig.6. The recognized liver regions are accurate. The liver regions were extracted from the original image using the output image. Figure 7 shows the extracted image of the liver. The second post-processing such as the closing was carried out using the fifth type rules and the liver region which contained the abnormal regions was obtained as shown in Fig.8. Figure 9 shows the extracted image of the liver. The candidate image region of the liver cancer were extracted from Fig.9 using Fig.7 and shown in Fig.10.

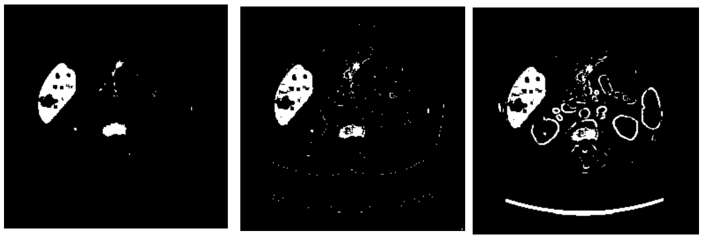
3.2 Recognition results of the conventional neural network trained using the back propagation algorithm

A conventional neural network trained using the back propagation algorithm was applied to the same recognition problem and the recognition results were compared with the results obtained using the revised GMDH-type algorithm. The conventional neural network had a three layered architecture and the same five input variables were used in the input layer. The learning calculations of the weights were iterated changing structural parameters such as the number of neurons in the hidden layer and the initial values of the weights. The output images, when the numbers of neurons in the hidden layer (m) are 5, 7 and 9, are shown in Fig.11. These images contain more regions which are not part of the liver. Note that, in case of the conventional neural network, we obtain many different output images for various structural parameters of the neural network and many iterative calculations of the back propagation are needed for various structural parameters in order to find more accurate neural network architecture.



(a) m=5 (b) m=7 (c) m=9

4. CONCLUSION

In this paper, the revised GMDH-type neural network algorithm using knowledge base for the medical image diagnosis was proposed and it was applied to the medical image diagnosis of the liver cancer and the results of revised GMDH-type neural network were compared with those of the conventional sigmoid function neural network trained using the back propagation algorithm. The revised GMDH-type neural network architecture fitting the characteristics of the medical images is organized using the knowledge base for the medical image diagnosis. It was shown that the revised GMDH-type neural network algorithm was accurate and a useful method for the medical image diagnosis of the liver cancer.

Abstract: The purpose of this study is to use seven different sensitivity analyses to find out the important variables to establish a comprehensive and objective assessment method. After pre-filtering, we obtained 4095 data for building this ensembled neural networks **(**ENN) model. The data has been divided into 60% data for training, 20% data for validation, and 20% data for testing. The eleven inputs, including response time, on-scene time, patient transfer time, time to cardiopulmonary resuscitation (CPR), CPR on the scene, using drugs, age, gender, using airway, using automated external defibrillator (AED), and trauma type, and one output variable have been selected as ENN model structure. The results have been shown CPR on the scene, using drugs, on-scene time, and using airway in the top four of these 11 important variables. Moreover, these four variables have also been shown significant differences when we use traditional one variable statistics analysis for these variables.

Keywords: Emergency medical system, ensembled neural networks, sensitivity analysis

I. INTRODUCTION

Fire Department, New Taipei City Government started to build a new system of recording pre-hospital cardiopulmonary stop patients' data in 2007. Until June 2011, the system has collected more than 9,000 data of the OHCA (out-of-hospital cardiac arrest) patients, including patients' basic characteristics, emergency treatment, the basic information of ambulance staff and patients' recovery treatment. Therefore, this study will target on analyzing out-of-hospital cardiac arrest patients data, and focus on the distribution of the incident, treatment, and the relationship between survival rate and the relevant characteristics of OHCA patients. Because of many uncertain factors, irregular non-linear characteristics, and the complex relationship of variables, it is difficult to use traditional mathematical equations and analytical methods. Hence, it must more carefully select the characteristics of the method. According to our previous studies [1-3], artificial neuronal network (ANN) is one of the most popular systems to deal with the nonlinear and non-stationary problems. It can be used to model the complex relationships between the inputs and outputs data of the system. An ensembled neural network (ENN) is a learning paradigm where a collection of a number of neural networks is trained for the same task. One theory behind using ENN is that several less accurate networks that are diverse can be combined into a more-accurate ENN. Moreover, we use seven different sensitivity analyses to find out the important variables to establish a comprehensive and objective assessment method. Then, we can understand which variables cause the survival rate or Glasgow Coma Scale (GCS) changes by build a model of ENN.

II. METHODOLOGY

(A) Choosing variables

According to previous research [3,4] and the information recorded in the OHCA patients in Fire Department of New Taipei City Government, the eleven inputs, including response time, on-scene time [3], patient transfer time [4], time to cardiopulmonary resuscitation (CPR), CPR on the scene, using drugs, age, gender, using airway, using automated external defibrillator (AED) [5], and trauma type, and one output variable have been selected as ENN model structure.

(B) Data pre-processing

Although we have 9000 patients in the database, we have only 4,095 complete data in the database after data cleaning. Then we build an ensembled neural network. The data is divided into three parts which were 60% data for training, 20% for validation, 20% for testing as shown in Fig. 1. Testing data do not need to pass through neural network to learn, so we do not sample data by random. The remaining 80% data are divided into 60% of training data and 20% validation data by random sampling. Then we selected topology structure of neural network model, and trial and error can help us for screening each structure [6]. There is a classic topology called pyramid. In many literature records, this method has better convergence and predictability. The pyramid means that the neurons of input layer are more than the neurons of hidden layer, and the neurons of hidden layer is more than the neurons of output layer [7].

(C) ROC analysis

We don't know the performances of model after building neural network model. So we applied ROC (receiver operating characteristic) curve analysis to find out the threshold at each model and estimate the discrimination power of the prediction models. We calculated the sensitivity (SEN), specificity (SPE), positive prediction value (PPV), and negative prediction value (NPV) of each model at the best threshold. Then we use this threshold to separate 0 and 1 for the each output that 0 is death and 1 is alive. Finally, we calculated total accuracy as the discrimination power of the prediction models.

(D) Ensembled neural network model

Although neural network is powerful, it's unstable due to random initial weight problems. Scholars have criticized for this long time. Ensembled neural networks are built by the group of neural networks to solve this problem. The topology structure of ENN is chosen one hidden layer with 8 nodes via trial-and-error method so that we choose 11-8-1 structure for this model. Moreover, the one output variable has been selected 5 different conditions (i.e., 2hr or 24 hr survival rate, or 24hr, 48hr, and 72 hr GCS). Each training data and validation data are used to train 20 networks with different initial weights. Then, 100 artificial neural networks (ANN) have been trained for each network. The learning effect of each network is tested by the testing data to examine the generalization of the network, and the best network in each training data and validation data is selected to be combined into the ensembled model [8, 9] as shown in Fig. 1.

(E) Sensitivity analysis

Sensitivity analysis can find the important parameters in the model. It works by observing the input variables how to impact on the output. We use seven different methods for sensitivity analysis. Firstly. We use the Morris method which is a randomized design that has proved to be an efficient and reliable technique to identify and rank important variables [10, 11]. Secondly, there are three methods to improve Morris method which are set the minimum, maximum, and mean values, while other variables have not changed. The root means square error of the network is assessed. Then the changed of RMSE is calculated. We can rank the input variables by the changed of RMSE. The more important variable is bigger changed. Finally, the rest three methods which are Perturb's method [13], connection weights [14], and Garson algorithm [15], can be seen more details in our previous study [16].

III. RESULTS

We have built five ensembled neural network models for different outputs. After building this ENN model, we use testing data to calculate this five outputs accuracy and the results show the accuracy is 68%, 76%, 80%, 86%, and 89%. The highest accuracy is 72 GCS model of prediction, and we use this model to do seven different sensitivity analysis. Finally, we use vote method to sum these 7 sensitivity methods via adding together the index number of ranked variables in seven methods of sensitivity analysis, and the more important variable has a smaller vote number. The results have been shown CPR on the scene, using drugs, on-scene time, and using airway in the top four of these 11 important variables as shown in Table 1. Moreover, these four variables have also been shown significant differences when we use traditional one variable statistics analysis for these variables.

IV. CONCLUSION

In conclusion, although the results of top four important inputs are consistent with one variable statistics analysis, the result of sensitivity analysis still has not been verified by experts. Hence, a comprehensive discussion with medical doctors who are experts in emergency medical system is still needed, perhaps to refine the ENN model or methods of sensitivity analysis, and certainly to see how widely the model and these methods are applicable.

Abstract: In this study, we proposed an analog complementary metal oxide semiconductor (CMOS) circuit based on the pheromone source location of the silkmoth. The analog circuit is achieved by the circuit for the threshold processing using the operational amplifier. Since the proposed circuit consists of the smell sensor, five metal oxide semiconductor (MOS) transistors and four resistors, the proposed circuit is simple structure. The test circuit was fabricated on the breadboard by discrete MOS transistors and resistors. The measured results of the test circuit showed that the output voltage becomes large when the smell sensor detects the smell of the target. The output voltage of the test circuit was approximately equal to the output signal of the model based on the pheromone source location of the silkmoth. The measured results showed that the proposed circuit can control the motor. In the future, the novel compact target tracking sensor can be achieved by applying the proposed circuits based on the pheromone source location of the silkmoth and the previous circuit based on the biological vision and auditory systems.

Keywords: analog circuit, pheromone source location, smell detection

1 INTRODUCTION

It is necessary for robotics system, monitoring system and other systems to process information at high speed. High speed processing is easily achieved in the biological system because the information processing is performed in massively parallel nerve networks with a hierarchical structure.

Recently, the simple complementary metal oxide semiconductor (CMOS) circuit for tracking the target [1]-[3] was proposed based on the biological vision and auditory systems. The proposed circuit can capture and track the target by processing information of the image and the sound. However, the circuit cannot track the target in the case that the information of the image and the sound is not acquired.

In such cases, the animal can track the target by using information of the smell. Recently, the model [4],[5] for detecting the position of the smell of the object was proposed based on the pheromone source location of the silkmoth.

In the case that the silkmoth detects the pheromone, the silkmoth goes straight on toward the pheromone source, the silkmoth is turned zigzag, and the silkmoth revolves around the pheromone source. The model was proposed based on such action pattern.

In this study, we proposed an analog CMOS circuit based on the pheromone source location of the silkmoth. The test circuit was fabricated on the breadboard by discrete MOS transistors and resistors. The measured results of the test circuit showed that the output voltage becomes large when the smell sensor detects the smell of the target. The output voltage of the test circuit was approximately equal to the output signal of the model based on the pheromone source location of the silkmoth.

2 MODEL

We describe in this section the pheromone source location of the silkmoth. It is considered that we can propose simple circuit by mimicking the information processing of the insect brain because the construction of the insect brain is simple.

Figure 1 shows the action pattern of the silkmoth for detecting the pheromone source. The silkmoth has the sensor which responds with the pheromone. The sensor generates the constant voltage (pulsed signal) when the pheromone is detected by the sensor.

When the silkmoth detects the pheromone, the silkmoth goes straight on toward the pheromone source until the position *a*. Other sensor responds with the pheromone when the silkmoth arrive at the position *a*.

In the case that the right sensor responds with the pheromone, the silkmoth turns toward the right. In the

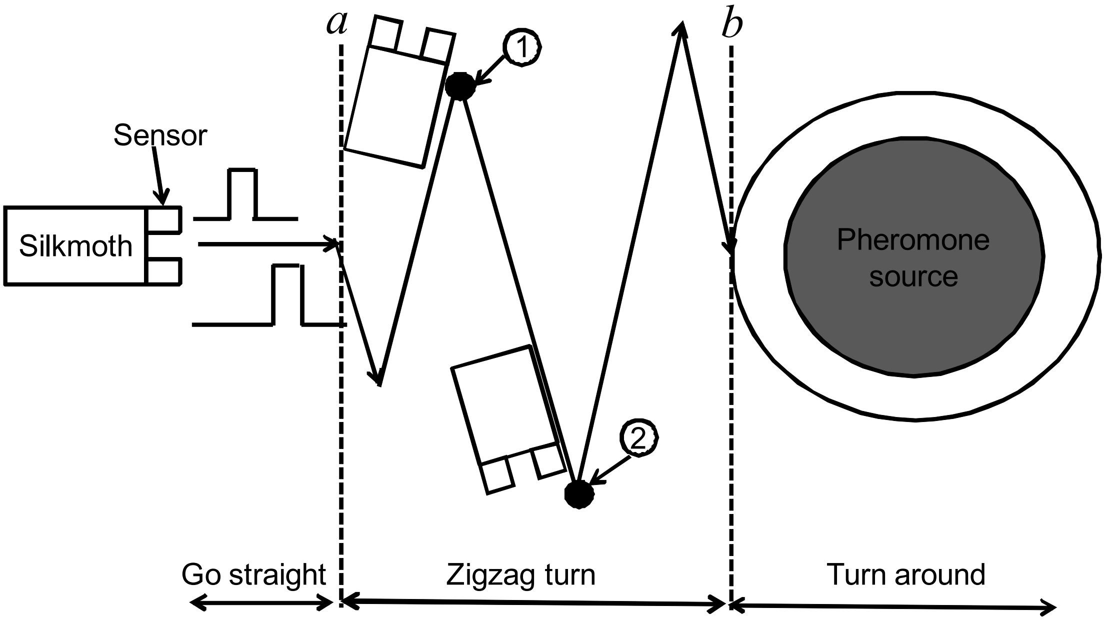

Fig. 1. The action pattern of the silkmoth for detecting the pheromone source

case that the left sensor responds with the pheromone, the silkmoth turns toward the left.

In position 1, the silkmoth turns toward the right since the right sensor responds with the pheromone. In position 2, the silkmoth turns toward the left since the left sensor responds with the pheromone. In the region from position *a* to position *b*, the silkmoth is turned zigzag.

In position *b*, both sensors respond with the pheromone, and the silkmoth detects the pheromone source. Then, the silkmoth revolves around the pheromone sources.

3 CIRCUIT

To realize the action pattern of the silkmoth, we proposed the analog CMOS circuit which outputs the constant voltage (pulsed voltage) when the smell is detected. The proposed circuit is shown in Fig. 2. The analog circuit is achieved by the circuit for the threshold processing using the operational amplifier. Since the proposed circuit consists of the smell sensor, five MOS transistors and four resistors, the proposed circuit is simple structure. The smell sensor is used as the input part. Four resistors are used to set the voltages.

The voltage V_1 is generated by the smell sensor. When the smell sensor detects the smell, V_1 becomes large. The voltage V_2 is set to the constant voltage. V_2 is the threshold voltage.

When V_1 is smaller than V_2, the output voltage V_{out} becomes 0. When V_1 is larger than V_2, V_{out} shows the constant voltage.

Thus, the proposed circuit outputs the constant voltage when the smell sensor detects the smell. By using two proposed circuit, we can develop the compact system which has the same function in Fig. 1.

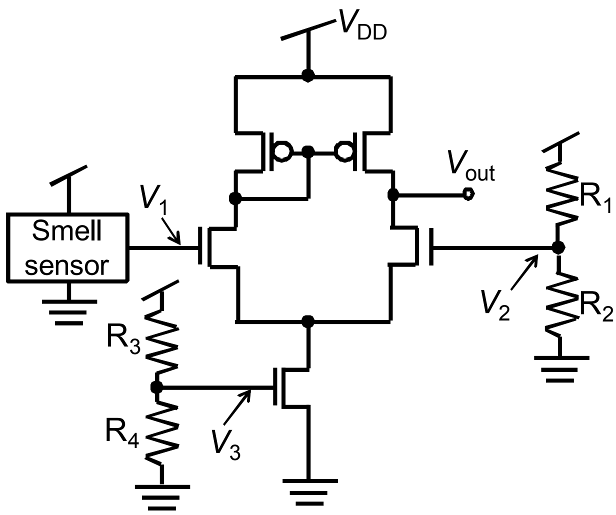

Fig. 2. The proposed circuit

4 MEASURED RESULTS

The test circuit was fabricated on the breadboard by discrete MOS transistors and resistors. Figure 3 shows the photograph of the test circuit. The supply voltage V_{DD} was set to 5 V. By setting to R_1=15 kΩ and R_2=15 kΩ, V_2 was set to 2.5 V. By setting to R_1=3 kΩ and R_2=1 kΩ, V_3 was set to 1.25 V. The ethanol was utilized as the smell source. The distance between the smell sensor and the ethanol was set to 1 m.

Figure 4 shows the output voltage V_{out} of the test circuit. V_{out} becomes the constant voltage (5 V) when the smell sensor detects the smell of the target. The output voltage of the test circuit was approximately equal to the output signal of the model based on the pheromone source location of the silkmoth. Thus, the measured results of the test circuit showed that the proposed circuit can operate normally.

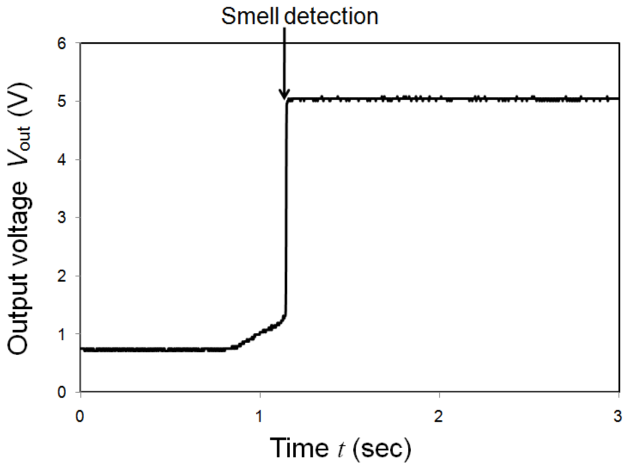

Fig. 4. Measured result of the test circuit

Figure 5 shows the photograph of the test circuit and the motor. The motor is utilized to the system such as the target tracking, mobile robot and others. The motor rotated when the smell sensor detected the smell. It was clarified that the motor can be controlled by the output signal of the proposed circuit.

5 CONCLUSION

We proposed in this study an analog CMOS circuit based on the pheromone source location of the silkmoth. The analog circuit is achieved by the circuit for the threshold processing using the operational amplifier. Since the proposed circuit consists of the smell sensor, five MOS transistors and four resistors, the proposed circuit is simple structure. The smell sensor is input part and four resistors are used to set the voltages. The test circuit was fabricated on the breadboard by discrete MOS transistors and resistors. The measured results of the test circuit showed that the output voltage becomes large when the smell sensor detects the smell of the target. The output voltage of the test circuit was approximately equal to the output signal of the model based on the pheromone source location of the silkmoth. It was clarified from the measured results that the motor can be controlled by the proposed circuit. Thus, we can achieve the novel compact system which has the same functions of the pheromone source location of the silkmoth by using two proposed circuit. In the future, the novel compact target tracking sensor can be achieved by applying the proposed circuits based on the pheromone source location of the silkmoth and

Abstract: This paper discusses stability of an adaptive type neural network direct controller in the viewpoint of its folding behavior. First, I discuss the stability for the nonlinear plant and the nonlinear neural network. This discussion confirms that we can include the plant Jacobian problem into the tuning problem of the parameter determining the neural network learning speed. This is because it was confirmed that the direct controller has the folding behavior and the sign of the slope of a part of plant inverse characteristics learned by the neural network dose not change. This means that the sign of the plant Jacobian dose not change. Next, I assume input output relations of the neural network are linear and present the detail of the stability condition. This assumption may not be practical, but it is helpful for understanding of the relationship between the plant Jacobian and the parameter tuning.

Keywords: Neural network, Controller, Learning, Adaptive

I. INTRODUCTION

Many studies have been undertaken in order to apply both the flexibility and the learning capability of neural networks to control systems. We seem to believe that a neural network learns an inverse dynamic of a target plant in a servo level neural network controller application. This is because the target plant dynamics can be cancelled by this learned inverse dynamics if the neural network can learn it. On the other hand, a practical plant generally has a nonlinear dynamics and it is mathematically expressed a many-to-one function whose more than one input values correspond to one output value. There is no inverse function of such function. For this problem, we confirmed that the neural network has the folding behavior in the neural network direct controller through the use of the sine wave as a nonlinear plant.[1] This behavior is that the neural network learns only one branch (; a part of the inverse characteristics and it can be expressed as a one-to-one function mathematically) of the inverse characteristics of the target plant in order to obtain whole plant output. When the neural network realizes such input output mapping, the whole inverse characteristics of the target plant seem to be folded into one branch of the inverse characteristics. This behavior means that we can realize an ideal control system if the neural network can learn only one inverse branch of the plant. Other remarkable point was also confirmed that the sign of the slope of one branch dose not change.[1] That is, the sign of the plant Jacobian (; the derivative of the output with regard to the input) of the branch learned by the neural network of the direct controller dose not change. This fact seems to realize the learning of the neural network direct controller without the direct object plant modeling. The complex structures of the forward and inverse modeling, the feedback error learning and so on are not necessary with regard to realize the neural network learning. However, our previous papers pointed out the possibility of this realization and we did not show the discussion about its stability.

Thus, this paper discusses the stability of the adaptive type neural network direct controller[2] in the viewpoint of the folding behavior. In the second chapter, I discuss the stability for the nonlinear plant and the nonlinear neural network. This discussion confirms that we can include the plant Jacobian problem into the tuning probelm of the parameter determining the neural network learning speed. This is because the sign of the slope of the learned branch dose not change and the sign of the plant Jacobian learned by the neural network of the direct controller dose not change.[1] In the third chapter, I assume the neural network is linear. This assumption may not be practical, but it is helpful for understanding of the relationship between the plant Jacobian and the parameter tuning. This is because this assumption can realize the more details of the stability analysis.

II. LEARNING OF NEURAL NETWORK DIRECT CONTROLLER AND FOLDING BEHAVIOR

Figure 1 shows a structure of the neural network direct controller. As shown in fig.1, the neural network output is the plant input and the learning of the neural network performs so as to minimize the error between the plant output and the desired value (teaching signal). If the learning of the direct controller performs well (equals that the plant output becomes to be the desired value), the neural network of the direct controller obtains a part of the inverse characteristics of the plant dynamics as mentioned in my previous paper.[1]

This paper selects the steepest descent method as the neural network learning rule. It is shown in the following equation.

$$\frac{dW}{dt} = -\eta \frac{\partial J}{\partial W} \tag{1}$$

Where W is the weight of the neural network, η is the parameter determining the learning speed and J is the cost function. This cost function is the square error between the plant output Y and the desired value Yd.

$$\frac{dJ}{dt} = \frac{\partial J}{\partial W}\frac{dW}{dt} \tag{2}$$

If the above equation (2) is satisfied, we can derive the following equation from eq.(1)

$$\frac{dJ}{dt} = -\eta \left(\frac{\partial J}{\partial W}\right)^2 \tag{3}$$

As shown in the above equation, since we can select that the parameter η is the positive value, the cost function J decreases as time progress. That is, the learning rule of the neural network is stable and the plant output becomes to be close to the desired value as time progress because the cost function J is the square error between the plant output and the desired value.

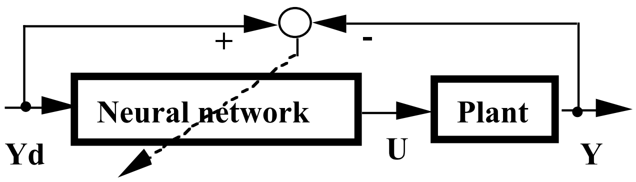

Fig.1 Scheme of neural network direct controller.

If we use an analog hardware as the neural network, we may realize the learning rule of eq.(2). However, most of the neural network controllers use the computer software since it is useful. In this case, the neural network learning rule is expressed as the following equation.

$$W(k+1) = W(k-d) - \eta_0 \frac{\partial J(k)}{\partial W(k-d)} \tag{4}$$

Where k is the sampling number and d is the dead time of the plant. Since this paper selects the adaptive type neural network, the weight of the neural network is changed at every several sampling time as shown in eq.(4). The cost function J(k) is defined as follows;

$$J(k) = \frac{1}{2}\varepsilon^2(k) \tag{5}$$

$$\varepsilon(k) = Yd(k) - Y(k) \tag{6}$$

Where Y is the plant output, Yd is the desired value and ε is the output error between them. Here, when the following eqs.(7) and (8) are assumed, we can obtain eq.(9) from eq.(4).

$$\frac{dW(k-d)}{dt} \cong w(k+1) - w(k-d) \tag{7}$$

$$\frac{dJ(k)}{dt} \cong \frac{\partial J(k)}{\partial W(k-d)}\frac{dW(k-d)}{dt} \tag{8}$$

$$\frac{dJ(k)}{dt} \cong -\eta_0 \left(\frac{\partial J(k)}{\partial W(k-d)}\right)^2 \tag{9}$$

As shown here, although we select the discrete time control system, if the eqs.(7) and (8) are satisfied, the plant output becomes to be close to the desired value as learning progress.

However, it is difficult to realize the learning rule eq.(4) in the direct controller when the plant characteristics is unknown. It is because $(\partial J(k)/\partial W(k-d))$ can not be calculated. As the practical solution, we can use the following equation in the replace of eq.(4).

$$W(k+1) = W(k-d) + \eta\, \varepsilon(k) \frac{\partial U(k-d)}{\partial W(k-d)} \tag{10}$$

Where U is the plant input. It equals the neural network output in the neural network direct controller as shown in fig.1. We must tune the parameter η in the replace of η_0 in eq.(4) and we can calculate eq.(10). It is because $(\partial U(k-d)/\partial W(k-d))$ can be determined by the neural network structure and this is known. The meaning of eq.(10) is explained in the following eq.(11) if eq.(12) is satisfied.

$$\eta = \eta_0 \frac{\partial Y(k)}{\partial U(k-d)} \tag{11}$$

$$\frac{\partial J(k)}{\partial W(k-d)} = \frac{\partial J(k)}{\partial Y(k)}\frac{\partial Y(k)}{\partial U(k-d)}\frac{\partial U(k-d)}{\partial W(k-d)} \tag{12}$$

$$\frac{\partial J(k)}{\partial Y(k)} = -\varepsilon(k) \tag{13}$$

From the similar way of eqs.(7)(8) and (10), we can obtain the following equation.

$$\frac{dJ(k)}{dt} = \eta\, \varepsilon(k) \frac{\partial J(k)}{\partial W(k-d)}\frac{\partial U(k-d)}{\partial W(k-d)} \tag{14}$$

From eqs(11)-(14), the following equation is obtained.

$$\frac{dJ(k)}{dt} = -\eta \frac{\partial Y(k)}{\partial U(k-d)} \left(\varepsilon(k) \frac{\partial U(k-d)}{\partial W(k-d)}\right)^2 \tag{15}$$

Where ($\partial Y(k)/\partial U(k\text{-}d)$) is the derivative of the plant output Y with regard to the plant input U and it is called the plant Jacobian. As shown in eq.(15), if $\eta(\partial Y(k)/\partial U(k\text{-}d))$ is positive, the cost function J decreases as time progress and the plant output becomes to be close to the desired value. That is, the neural network learning is stable and it performs well,

If the plant is linear system, it is well known that the plant Jacobian ($\partial Y(k)/\partial U(k\text{-}d)$ is constant. It is not difficult to tune the parameter η for the linear plant. However, if the plant is nonlinear, the plant Jacobian is not constant and it may be changed from negative to positive or from positive to negative in the neural network learning progress. Thus, the learning rule eq.(10) seems to be not practical because it seems to be difficult to tune the parameter η. However, it was confirmed that the neural network direct controller has the folding behavior.[1] It is not necessary for neural network learning of the direct controller to obtain whole plant inverse characteristics. If the neural network obtains only one branch (a part of the plant inverse characteristics and it is mathematically expressed as one to one function), the plant output matches with the desired value for whole region. The plant Jacobian in eq.(15) is referred to the branch which the neural network must learn. This is because the plant is controlled within this branch. The sign of its slope is not changed because the branch is expressed as one to one function and it monotonously increases or decreases. From eq.(15), the choice of the parameter η is positive or negative to stabilize the neural network learning. It is not so difficult to tune the parameter η.

As shown in eq.(15), the plant Jacobian effect can be included into the tuning of the parameter η and we can use the learning rule eq.(10). However, the assumptions eq.(7) and (8) seem to be strained. In particular, eq.(7) may not be satisfied around the weights which the neural network converge to. In the next section, I discuss the stability condition of the adaptive type neural network direct controller. This discussion uses the assumption that the input output relation of the neural network is linear. It is because it is difficult for the nonlinear neural network to analyze its stability condition, but the discussion of the next session is helpful to understand the plant Jacobian effect and the meaning of the learning rule eq.(10).

III. STABILITY CONDISION OF ADAPTIVE TYPE NEURAL NETWORK DIRECT CONTROLLER

Previous section shows the discussion of the stability of the neural network direct controller and its folding behavior, but the assumption of eqs.(7) & (8) seems to be strained. In order to discuss its stability condition, this section selects a three layer neural network whose neurons have a liner input output relation. This linear assumption may not be practical, but it is helpful for understanding of the neural network stability condition. The neural network is expressed as the following equation by use of this liner assumption.

$$U(k) = \omega^T(k)\ W(k)\ I(k) \tag{16}$$

Where ω is the weight vector between the hidden layer and the output layer, W is the weight matrix between the input layer and the hidden layer and I is the input vector of the neural network.

The following nonlinear plant is selected in this paper.

$$Y(k) = f(Y(k\text{-}d), \bullet\bullet\bullet, Y(k-d-n), U(k-d), \bullet\bullet\bullet, U(k-d-m)) \tag{17}$$

Where n & m are the plant orders and f is the nonlinear function which expresses the plant nonlinearity. The learning rule is derived as the following equations based on eqs.(10)-(13) and the linear assumption.

$$W(k+1) = W(k-d) + \eta\,\varepsilon(k)\omega(k-d)I^T(k-d) \tag{18}$$
$$\omega(k+1) = \omega(k-d) + \eta\,\varepsilon(k)W(k-d)I(k-d) \tag{19}$$

Here, we define the parameter error vector ζ as the following equation.

$$\zeta^T(k) = \omega_0^T\, W_0 - \omega^T(k)\ W(k) \tag{20}$$

Where ω_0 and W_0 are the weight vector and the weight matrix when the neural network is finished to converge.

The following discussion is described about the local stability when the neural network almost converges to the weight vector ω_0 and matrix W_0. From this assumption, the output error is expressed as follows;

$$\varepsilon(k+d) \cong \frac{\partial Y(k+d)}{\partial U(k)} \Delta U(k) \tag{21}$$

Where $\Delta U(k)$ is the difference between the present plant input and the plant input when the neural network is finished to converge. This $\Delta U(k)$ is sufficiently small because of the local stability. We assume the follows;

$$\begin{aligned} \Delta U(k) &\cong (\omega_0 - \omega(k))^T (W_0 - W(k))\ I(k) \\ &\cong (\omega_0^T W_0 - \omega_0^T W(k) - \omega^T(k)\ W_0 + \omega^T(k)\ W(k))\ I(k) \end{aligned} \tag{22}$$

From the local stability, we assume that both ω_0 and W_0 are almost equal to ω and W for the second and third terms of eq.(22). From eqs.(21)(22) and this assumption, we can obtain the following equation.

$$\varepsilon(k+d) = \frac{\partial Y(k+d)}{\partial U(k)} \zeta^T(k) I(k) \tag{23}$$

From the local stability, the output error ε is sufficiently small and ε^2 is almost 0. From this assumption and eqs.(18)(19) & (23), we obtain the following equation.

$$\omega^T(k+1)\, W(k+1) = \omega^T(k-d)\, W(k-d) + \eta \frac{\partial Y(k)}{\partial U(k-d)} \zeta^T(k-d)\, \xi(k-d) \tag{24}$$

$$\xi(k) = I(k)\, \omega^T(k)\, \omega(k)\, I^T(k) + I(k)\, I^T(k)\, W^T(k)\, W(k) \tag{25}$$

From eqs.(20) and (24), the following equation is derived.

$$\zeta^T(k+1) = \zeta^T(k-d)(E - \eta \frac{\partial Y(k)}{\partial U(k-d)} \xi(k-d)) \tag{26}$$

Where E is the identity matrix. When $\phi(k)=\zeta^T(k)\ \zeta\ (k)$ is selected as a candidate of the Lyapunov function, we can obtain the following equation.

$$\Delta\varphi = \varphi(k+1) - \varphi(k-d) = \zeta^T(k-d) Q \zeta(k-d) \tag{27}$$

$$Q = -2\eta\, (\frac{\partial Y(k)}{\partial U(k-d)})\, \xi(k-d) + \eta^2 (\frac{\partial Y(k)}{\partial U(k-d)})^2 \xi(k-d) \xi^T(k-d) \tag{28}$$

Since ξ defined by eq.(25) is the real symmetric matrix whose eigen values are not negative, there is a real orthogonal matrix V so as to $\xi = V^{-1}\beta V$ where β is a diagonal matrix whose diagonal elements are the eigen values of ξ. From eqs.(27) and (28), the following equation is derived.

$$Q = V^{-1}(\eta^2 (\frac{\partial Y(k)}{\partial U(k-d)})^2 \beta^2 - 2\, \eta \frac{\partial Y(k)}{\partial U(k-d)} \beta) V \tag{29}$$

When λ_i is defined by the eigen value of β, λ_i is not negative and the rank of β is 1. That is, the positive λ_i is 1 and this is the maximum eigen value λ_0 which is not 0. From eqs.(27)-(29), when the following equation is satisfied, $\Delta\phi$ is not positive and the neural network controller is stable.

$$0 \le \eta (\frac{\partial Y(k)}{\partial U(k-d)}) \lambda_0 \le 2 \tag{30}$$

As shown in eq.(30), the plant Jacobian ($\partial Y(k)/\partial U(k-d)$) is related to the stable condition. Its sign is important because the parameter η must be changed if its sign is changed in order to stabilize the neural network direct controller. However, my previous paper confirmed that the neural network of the direct controller has the folding behavior. It learns only one branch of the plant inverse in order to express whole plant characteristic. This branch is expressed as one to one function mathematically. The sign of the plant Jacobian is not changed. This is because the branch learned by the neural network monotonously increases or decreases. From eq.(30), it is not necessary to change the sign of the parameter η because λ_0 in eq.(30) is positive.

There is a maximum of absolute value of the plant Jacobian ($\partial Y(k)/\partial U(k-d)$) if the branches learned by the neural network are continuous. If neither this maximum nor λ_0 are not 0, we obtain the following stability condition.

$$0 \le \eta \le \frac{2}{P\lambda_0} \quad (0 < P), \qquad \frac{2}{P\lambda_0} \le \eta \le 0 \quad (0 > P)$$
$$P = \left| \frac{\partial Y(k)}{\partial U(k-d)} \right|_{Max} \tag{31}$$

where P is the maximum of absolute value of the plant Jacobian ($\partial Y(k)/\partial U(k-d)$). As shown in eq.(31), if we tune the parameter η so as to satisfy eq.(31), we can stabilize the neural network direct controller. This is because the maximum eigen value λ_0 is positive and it can be calculated within the neural network learning.

IV. CONCLUSION

This paper discusses the stability of the adaptive type neural network direct controller in the viewpoint of the folding behavior. First, I discuss the stability for the nonlinear plant and the nonlinear neural network. This discussion confirms that we can include the plant Jacobian problem into the tuning problem of the parameter determining the neural network learning speed. This is because the neural network direct controller has the folding behavior. However, the used assumption may be strained around the converged neural network weights. Thus, I assume the input output relation of the neural network is linear and present the more detail of the stability condition of the adaptive type neural network controller.

Abstract: Designing high-quality products/processes at low cost leads to increasing market share and gaining competitive advantage. Thermoforming of plastic sheets has become an important process in industry because of their low cost and good formability. However there are some unsolved problems that confound the overall success of this technique. Nonuniform thickness distribution caused by inappropriate processing condition is one of them. In this study, results of experimentation were used to develop a process model for thermoforming process via a supervised learning back propagation neural network. An "inverse" neural network model was proposed to predict the optimum processing conditions. The network inputs included the thickness distribution at different positions of molded parts. The output of the processing parameters was obtained by neural computing. Good agreement was reached between the computed result by neural network and the experimental data. Optimum processing parameters can thus be obtained by using the neural network scheme we proposed. This provides significant advantages in terms of improved product quality.

Keywords: Polypropylene Foam, Thermoforming, Artificial Neural Network, Optimal Processing Parameters.

1 INTRODUCTION

Manufacturing strategy has been defined as the adoption of courses of action and the allocation of resources necessary for carrying out the goals [1]. Such a broad definition of strategy covers a multitude of decisions how can manufacturing contribute to the competitive advantage of this business. Manufacturing objectives cover such things as cost, quality, delivery and flexibility and usually there are trade-offs between them. Trade-off decisions are also required in a number of key areas in order to support the manufacturing objectives. Production planning/control and product design/engineer- ing are identified within the decision areas. These basic ideas (trade-offs and consistency of objectives/policies) have formed the foundation from which the current understanding of manufacturing strategy has developed.

Designing high-quality products/processes at low cost leads to increasing market share and gaining continuous customer loyalty. Robust design combines the experimental design techniques with quality loss consideration, is an engineering approach of quality improvement that seeks to obtain a lowest cost solution to the product design specification based on the customer's requirement. There is a significant amount of ongoing research in the area of the thermoforming [2] process in industry due to its low cost and good formability. However there are some unsolved problems that confound the overall success of this technique. Nonuniform thickness distribution caused by inappropriate processing condition is one of them. In this study, results of experimentation were used to develop a process strategy for thermoforming process via a supervised learning back propagation neural network. In the process, a thick sheet is clamped in a frame and is heated to a temperature well above its glass transition temperature such that it becomes rubbery and soft. It is then placed over a mold and is stretched to take on the contours of the mold, either by a plug assist or a differential pressure.

An inverse back-propagation neural network [3-5] was proposed to model the thermoforming process of polyethylene terephthalate (PET) materials and to predict the optimum processing parameters. The network inputs included the thickness distribution at different positions of molded parts. The output of processing parameters was obtained by neural computing. The network training was based on 47 sets of training samples and the trained network was tested with 10 sets of the test samples, which were different from the training data. The final goal of this study is to optimize the thermoforming process of PET sheets by using the neural network method, providing significant advantages in terms of improved product quality.

2 EXPERIMENTAL

A neural network is a computer system, which mimics the structure of human brain and imitates intelligent behavior [6]. It consists of many simple and highly connected neurons (processing elements or nodes), and processes information by its dynamic-state response to external inputs. It can deal with the problems of highly dimensional and nonlinear systems. The parallel distributed processing of the neural networks promises high computation rates provided by the massive parallelism, a greater degree of robustness or fault tolerance due to adapt and to continue to improve performance. The learning is based on samples, so it is especially suitable for the complicated process with a nontransparent mechanism. Therefore, neural networks, as one of most active branches of artificial intelligence in recent years, have been widely used in the process industries, including fault diagnosis and pattern recognition, process control and optimization, system modeling, and on-line measurement and prediction.

The earliest embryonic form of neural network was presented by a computer scientist named Rosenblatt (1958). Later, Minski and Papert (1969) claimed that the learning ability of ANN was very limited and could not even complete the basic functions of Exclusive OR gate. Hopfield and Tank (1985) proved that as long as appropriate network architecture was established and calculation of error function was defined, the network would be able to quickly obtain a good approximate solution. Rumelhart and McClelland (1986) were the first researchers to present the back-propagation network, and after that, ANN started to be widely applied to engineering fields such as physics, electronics, electric machinery, automatic control and so on [4,5].

A neural network is composed of many artificial neurons and links and can be formed into various types of network models. With learning, reasonable inference can be generated, making it very suitable to solve complex problems. Meanwhile, its nonlinear model is of high accuracy and has the advantage of accepting logical, numerical, order-relevant and order-irrelevant input, allowing for a wide range of adaptability and application. Currently, the most widely applied model is the Back-propagation Neural Network, a type of supervised learning network that is based on the concept of the gradient descent or steepest descent method, which minimizes the error functions of actual output and expected output. With the addition of hidden layers and the use of smooth and differentiable transfer function, the formula for the weight of the correction network can be derived from the gradient descent or steepest descent method.

In Fig.1 depicting the basic structure of ANN, $X=(x_1, x_2,\dots, x_n)$ is the input layer, and in each layer, the link of neural networks W_{ij} stands for the weight required for Unit *j* in one layer to move to Unit *i* in the previous layer. The functions of each layer are detailed as follows.

1. Input Layer: This represents the input variables of the network, and the numbers of processing units depend on the research problem, with the application of the linear transfer function, i.e., $f(x) = X$.
2. Hidden Layer: This represents the interaction between the processing units, and there is no standard method by which to determine the number of processing units. Generally, the best number can be decided by means of Trial and Error Method. Normally the number of hidden layer units is between (the number of input layer units + the number of output layer units)/2 ~ (the number of input layer units + the number of output layer units) x 2. In addition, due to the application of nonlinear transfer function, the network can either be more than one hidden layer or be designed to be without a hidden layer.
3. Output Layer: This represents the output variables. The number of processing units depends on the question, and the nonlinear transfer function is also used.

(Fig. 1 The structure of ANN)

An "inverse" neural network was proposed for system optimization in this study. Most neural networks use processing parameters as the inputs and molded product qualities as the computed outputs. We allocated inversely, the inputs and outputs in our model; i.e., assigned the product qualities as the inputs and the desired processing parameters as the outputs. The input variables in this research are the measured thickness profiles of molded parts at six different positions. The output variables include five different processing parameters: temperature of the heating pipe, vacuum pressure, plug moving speed, plug displacement, and thermal conductivity of the plug material. Thirteen nodes were selected for the hidden layer, which corresponds to two times the number of input variables plus one; i.e., the network 6-13-5 (six nodes in the input layer, thirteen nodes in the hidden layer, five nodes in the output layer) was chosen as the final structure, using a sigmoid function as its transfer function. By adopting an inverse neural network, we are able to determine the optimum processing parameter sets for the desired thickness profile of the parts.

3 RESULTS AND DISCUSSION

In this report, a model based on the ANN approach was used to predict an optimum setting of thermoforming parameters to achieve the optimum qualitative responses of polypropylene foams. Using the "inverse" neural network proposed in this study, we were able to predict the optimum set of processing parameters for the inputted part thickness distribution. In this study, forty-seven sets of data were used as training samples and the trained neural network was tested by 10 sets of data, which were different from the training samples. The network inputs included the thickness distribution at different positions of molded parts, and the output of the processing parameters was obtained by neural computing. To facilitate the training process, numbers were assigned to different plug materials: 1 for wood covered with woven blanket, 2 for a wood plug, and 3 for a phenol formaldehyde plug. The whole training procedure involved adjusting all weights on connections of the network according to the learning rule. The iteration continued until the computed outputs reached the required precision of agreement to the actual outputs. The test results are in Figs. 2-4 [7]. The results show good agreement to the actual measurement, except for the plug material sample in Fig. 4.

The most valuable result of this research is not only a development of a practical neural network for the thermoforming process of plastic sheets, but also a technique which has been proved to be suitable for modeling and predicting of the thermoforming process. It is valuable for the optimum control of the process and of practical significance to advanced thermoforming processes. Further research is suggested to consider the effect of different thermoplastic materials and assisting plug's geometry and temperature, because they may influence significantly the performance of the thermoforming of thermoplastic materials.

4 CONCLUSIONS

This study has proposed an inverse neural network model to predict optimum processing conditions. The network inputs included the thickness distribution at different positions of molded parts. The output of the processing parameters was obtained by neural computing. Good agreement was reached between the result computed by the neural network and the experimental data. By using the neural network strategy, one is able to optimize the thermoforming process of PET sheets, providing significant advantages in terms of improved product quality.

Abstract: Recently, researches on smell sense that is one of the sensory organs of man have been actively done. The KIII model is one of the olfactory models that is thought out by Freeman referring to a physiological structure of mammal's olfactory system. In this paper, we propose a commonly used feature extraction method that applies Fourier transformation to the behavior of the time series and also propose to use the dynamics of chaotic neuron instead of the Hodgkin-Huxley equation to reduce computation time. Our introduced structure of the chaotic neuron has the simple structure and that it makes possible the chaotic operation same as the Hodgkin-Huxley equation. Paying attention to the point that the human brain does a similar processing to any sense of information, the hand-written image recognition problem that uses the KIII model is adopted as the computation simulation. Through the computer simulation of the handwriting character classification, it is shown that the proposed method is useful in the point of both computation time and the recognition accuracy.

Keywords: Handwriting character classification, Freeman, KIII model, Fourier transformation, Chaotic neuron

I. INTRODUCTION

Recently, according to development of non-invasive measurement techniques (CT, PET, fMRI, NIRS etc.), experimental research on higher-order brain functions has been advancing dramatically and the latest researches have been used in many fields. One of those high-order systems, the olfactory system, has also come to be actively done. As a model of the olfactory system, there is KIII model proposed by Freeman et al. [1][3].

The KIII model has been modeled based on the physiological structure of the mammalian olfactory system, and there are many applications using pattern recognition ability of the olfactory system. For example, J.Fu et. al[2] combined KIII model and the electronic nose with chemical sensors, and applied it to discriminate six typical volatile organic compounds in Chinese wine. The KIII is also applied to Tea Classification problem (Yang et. al[4]), Face Recognition (Li et. al. [6]), On the other hand, response of the olfactory system has a chaotic nature [5][7], it has also attracted many researchers.

In this paper, we apply the KIII model to handwriting character classification. In the application of the KIII model mentioned above, they performed the pattern recognition by using standard deviation of time series response inside the KIII model corresponding to the inputted data which should be discriminated. In this paper, we propose to use Fourier transform as the feature extraction method.

On the other hand, in KIII model, output of the neuron is obtained by solving second order ordinary differential equations and as a result, that leads to the problem that enormous processing time is required. Therefore, in this study, we aim reduction of the processing time, maintaining the chaotic characteristic of each neuron, by adopting the simplified output formula.

II. KIII MODEL

KIII is a recurrent neural network model created by Freeman et al, based on biological olfactory structure [1]. The main parts of the neural olfactory neural system is composed of primary olfactory nerve (PON), olfactory bulb (OB) , anterior nucleus (AON), and prepyriform cortex (PC). According to the anatomic architecture, KIII network is a multi layer neural network model. Fig. 1 shows the structure of the KIII model, in which M, G represent mitral cells and granule

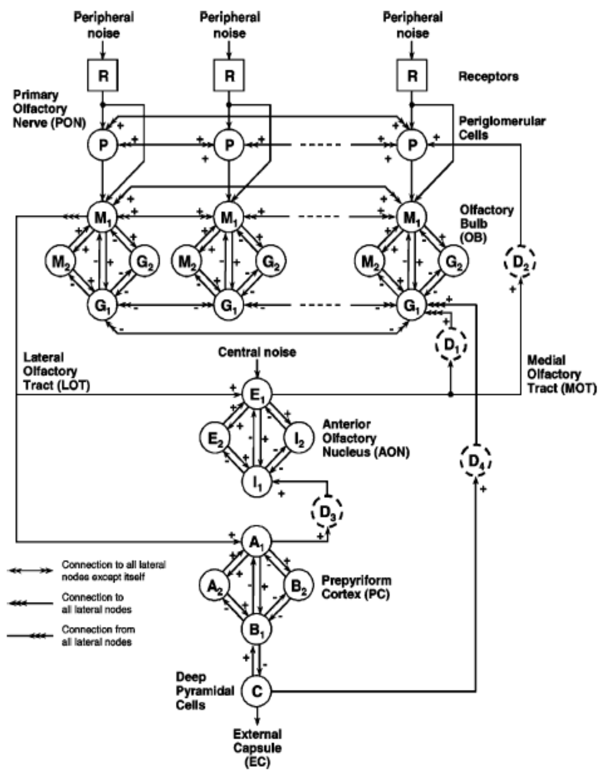

Fig. 1 Structure of the KIII Model (from [5][6])

cells in olfactory bulb.R represents the olfactory receptor, which offers input to the KIII model. E, I, A, B represent excitatory and inhibitory cells in anterior nucleus and prepytiform cortex, respectively. The KIII model based on the olfactory neural system is a high dimensional chaotic network. In this model, the interaction of connected nodes leads to a high-dimensional chaotic attractor. After learning from different patterns, the system will form several low-dimensional local basins[3]. Therefore, the memory for different patterns might be regarded as the formation of the local basins, while the recognition process refers to the transition from one basin to another.

The parameters of the KIII model, such as connection weights between different nodes, were optimized to fulfill features observed in lots of electro-physiological experiments [3]. Every nodes is described as a second order differential equation as follows:

$$\frac{1}{ab}[\ddot{x}_i(t)+(a+b)\dot{x}_i(t)+abx_i(t)]=\sum_{j\neq i}^{N} w_{ij}Q(x_j(t),q_j)+k_i r_i(t),$$

$$Q(x(t),q)=\begin{cases} q\left(1-\exp\left(-\dfrac{\exp(x(t))-1}{q}\right)\right), & x(t)>-x_0 \\ -1, & x(t)\le -x_0 \end{cases}, \qquad (1)$$

$$x_0=-\ln\left(1-q\ln\left(1+\frac{1}{q}\right)\right).$$

$x_i(t)$: state variable of the ith node, w_{ij}: the connection weight from j to ith node, a, b, q: constants derived by the electro-physiological experiments on biological olfactory system. k_i: coefficient as to the effect of the input, $r_i(t)$: input (external stimuli), N: the number of neurons

III. FEATURE EXTRACTION

Usually, when doing pattern recognition using the KIII model in general, we should create a feature vector from the characteristics of the behavior of M1 node dynamics.

Feature extraction by the standard deviation (Commonly used)

The state of OB layer mitral level is used as the strength of activity. The learning process only adjusts connection weights among the mitral. A modified Hebbian learning rule and a habituation rule are employed to KIII model.

When feature data are input to the KIII model with n channels, the behavior of each node is represented as an output time series as shown in Fig. 2. To get the characteristics of the kth channel's state, a value $SD(k)$ is extracted. The period with input patterns is divided into S segments (Fig. 2) and $SD(k)$ is the mean standard deviations of these segments. SD, composed of all the $SD(k)$ in the OB layer, depicts the activities of the all channels.

$$SD(k)=\frac{1}{S}\sum_{r=1}^{s} SD_{kr}, \quad k=1,\ 2,\ \ldots,\ n \quad , \qquad (2)$$

$$SD_m=\frac{1}{n}\sum_{k=1}^{n} SD(k), \quad SD=[SD(1),SD(2),\cdots,SD(n)]. \quad (3)$$

According to the modified Hebbian learning rule Eq. (4), the connection weights are adjusted.

$$\begin{aligned} &\text{IF} \quad SD(i)>(1+K)SD_m \quad \text{AND} \quad SD(j)>(1+K)SD_m \\ &\quad \text{THEN} \quad w'_{ij}=h_{Heb}, \quad w'_{ji}=h_{Heb} \\ &\quad \text{ELSE} \quad w'_{ij}=h_{hab}w_{ij}, \quad w'_{ji}=h_{hab}w_{ji} \end{aligned} \qquad (4)$$

w_{ij}, w'_{ij}: connection weights between M1 nodes before change and after one, respectively, K: bias, h_{Heb} : strengthening coefficient for Hebb learning, h_{hab} : weakening coefficient for refinement learning.

The learning for connecting weights continues while it is under changing.

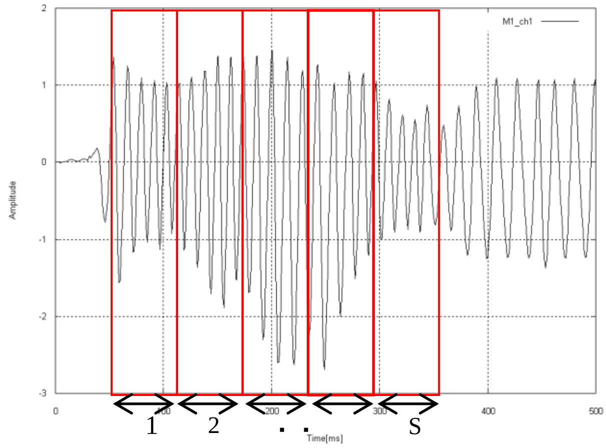

Fig. 2 Example of segmentation in the time-series behavior of the internal state of a M1 node

Fourier transform feature extraction method (Proposed)

Feature vectors are extracted as power spectrum and their frequency obtained by the discrete Fourier transform of time-series data of M1 node as shown in Fig. 3. Which shows an example of the power frequency spectrum.

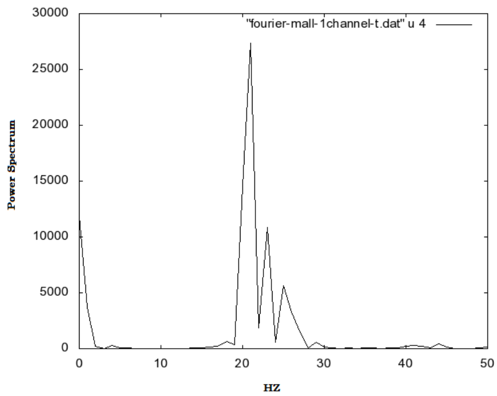

Fig.3 An example of power spectrum

IV. SIMPLIFICATION OF THE OUTPUT NONLINEAR FUNCTION OF THE NODE

The calculation of solutions of second order differential equations for determining the output of the neurons requires enormous processing time. This is a common problem in conventional method. Therefore, to reduce the computation time, we intend to simplify the second order differential equation. Furthermore, to produce chaotic response which are in the response of the above mentioned equations, we propose the two simplified equations referring to dynamics of chaotic neural network (CNN).

Dynamics of Chaotic neural networks

$$y_i(t+1) = ky_i(t) + \sum_{j=1}^{N} \omega_{ij} x_j(t) - \alpha x_i(t) + r_i(t)$$
$$x\ (t+1) = f\left(y(t+1)\right) \quad (5)$$

$y_i(t)$: internal state of the ith neuron, $x_i(t)$: output of the ith neuron, w_{ij}: connection weight from jth neuron to ith neuron, k: refractory decay coefficient, α: constant parameter, $r_i(t)$: input (external stimuli), N: the number of neurons, f: output function of a neuron.

Simplified equation I

$$y_i(t+1) = ky_i(t) + \sum_{j \neq i}^{N} \omega_{ij} Q(x_j(t), q_j) - \alpha x_i(t) + r_i(t)$$
$$x_i(t+1) = \frac{1}{1+\exp\left(-\dfrac{y_i(t+1)}{\varepsilon}\right)} \quad (6)$$

Simplified equation II

$$y_i(t+1) = ky_i(t) + \sum_{j \neq i}^{N} \omega_{ij} x_j(t) - \alpha x_i(t) + r_i(t) \quad (7)$$

V. HANDWRITING CHARACTER CLASSIFICATION

When performing the image pattern recognition using KIII model, there is a question of how to create input vectors of treating the image. In this research, two pre-treatment are carried to create the input vector.

Pixel Average (PA) method

By dividing the image to plural segments and taking the average of each pixel value of split images, we create input vectors which consist of them.

Discrete Cosine Transform (DCT) method

The DCT is one of ways to convert discrete signals into discrete frequency domain. It is mainly used for signal compression, in image processing, that is, the technique has been used in image compression such as

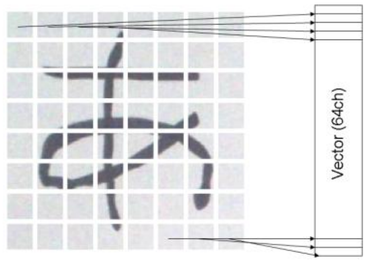

Fig. 4 Example of image segmentation

MPEG and JPEG. Compared to the discrete Fourier transform, this is characterized by the spectrum tend to be concentrated in specific frequencies. In the DCT, the DCT coefficients , that is, features in this research, are calculated by DCT basis functions and they are divided to the DC component (DC) and alternating component (AC). If you make the image DCT transform, the low frequency components (coefficients) are greater, conversely, high-frequency components become so smaller. The formula of DCT is shown in Eq. (8).

$$F_{k,l} = \sum_{j=0}^{N-1}\sum_{i=0}^{N-1} f_{ij}\phi_k[i]\phi_l[j]$$
$$f_{k,l} = \sum_{l=0}^{N-1}\sum_{k=0}^{N-1} F_{kl}\phi_k[i]\phi_l[j] \quad (8)$$
$$\phi_k[i] = \begin{cases} \dfrac{1}{\sqrt{N}} & k=0 \\ \sqrt{\dfrac{2}{N}}\cos\dfrac{(2i+1)k\pi}{2N} & k=1,2,\cdots,N-1 \end{cases}$$

We show the proposed system in Fig. 7.

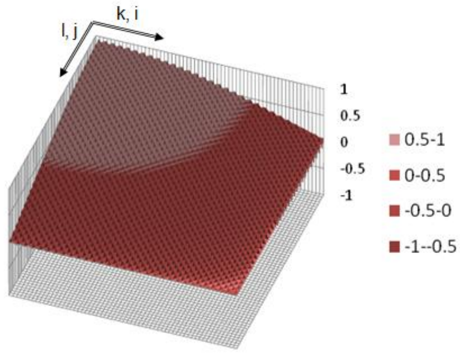

Fig.5 Values of DCT basis function (64×64) $\phi_k[i]\phi_l[i]$

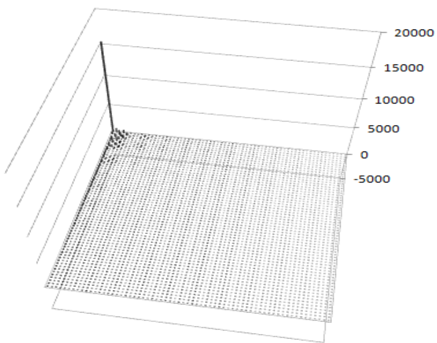

Fig.6 Example of DCT coefficients (64×64)

VI. COMPUTER SIMULATION

We confirm the usefulness of the proposed method under the conditions as follows,

・ Data format：bmp, ・ Data size：512×512
・ Subject：15 (Male), ・The number of channels : 64
・ The number of Japanese characters (refer to Fig.8)：
200 (= 10 males x 4 x 5 characters for training),
100 (= 5 males x 4 x 5 characters for testing)

Fig.8 Examples of hand writing images used in simulation

Simulation 1

We first verify usefulness of the Fourier transform comparing the standard deviation. Simulation results are shown in Table 1. The method using PA & FT is best.

Table 1 Success rates of 2 feature extraction methods

Model / Input feature extraction method	Standard Deviation	Fourier Transform
PA method	89.0%	94.0%
DCT method	84.0%	91.0%

Simulation 2

We next verify usefulness of two cases of simplified output functions of neurons comparing the conventional second-order differential equation. Simulation results are shown in Tables 2, 3 and 4.

Table 2 Success rates of the simplified KIII model I

Model / Input feature extraction method	α＝1.0 in Eqs. (6), (7)		α＝0.35 in Eqs. (6), (7)	
	SD	Fourier	SD	Fourier
PA method	51%	62%	47%	79%
DCT method	27%	58%	37%	62%

Table 3 Success rates of the simplified KIII model II

Model / Input feature extraction method	α＝1.0 in Eqs. (6), (7)		α＝0.35 in Eqs. (6), (7)	
	SD	Fourier	SD	Fourier
PA method	47%	68%	60%	61%
DCT method	40%	59%	34%	69%

Table 4 Computation times among 3 methods

Model	time(sec)
KIII model	3034
Simplified KIII model I	640
Simplified KIII model II	24

VII. DISCUSSION AND CONCLUSION

Recognition result of the feature vector extraction method by the Fourier Transform showed higher recognition rate than the conventional method, the Standard Deviation. In addition, processing times of the simplified two output functions of neurons introduced to make the enormous processing time of KIII model reduce are shortened by 1 / 150 of the conventional for the simplified formula I, 1 / 5 of the conventional for Formula II. However, the recognition rate of both simplified output functions came to be reduced.

Future work is as follows,

● Performance improvement of the proposed method making appropriate trade-off between improving the recognition rate and increasing the processing time, as increasing the number of dimensions of feature vectors.

Abstract: This paper presents a novel method for detecting corners in an image irrespective of the contrast. The corner detection method proposed by Kanade, Lucas, and Tomasi (KLT), Ando, and Harris corner detector are among the most widely used algorithms. They are all based on image gradients. Thus, the performances of those conventional approaches depend on the contrast of images. They work well for high-contrasted patterns, but have a difficulty in detecting low-contrasted corners. To overcome the problem, we propose to use unit gradient vectors (UGVs), instead of gradients, because UGVs are known to be a robust image feature and invariant to image contrast.

Keywords: corner detection, pattern recognition, unit gradient vectors.

1 INTRODUCTION

Corner detection is an important task in the field of digital image processing and computer vision. It finds various applications such as image matching, object recognition, motion estimation, etc [1]. Extracting corners can significantly reduce the computation cost in several applications [2]. Motion estimation also gains an advantage from this corner detection. Motion estimation can be performed correctly in an image area that contains a corner. On the other hand, it is difficult to estimate motions in an area that contains a straight edge boundary because of the so-called aperture problem. Thus, the computational cost can be reduced by performing motion estimation only on the image areas where a corner is present. There are several corner detectors that use image gradients. For instance, the corner detection method proposed by Kanade, Lucas, and Tomasi (KLT) utilizes the smaller eigenvalue of the 2×2 gradient covariance matrix defined locally within an image [3], [4]. Next, Ando's method makes use of the two eigenvalues of the 2×2 gradient covariance matrix [5]. The two eigenvalues are combined into a function in a normalized form. Thirdly, the Harris detector also uses the two eigenvalues [6]. Since these existing methods use image gradients, they depend on image contrast. Thus, they operate properly on high-contrasted corners, but it is truly difficult to detect low-contrasted corners.

In this paper, we propose to substitute unit gradient vectors (UGVs) for image gradients because UGVs is a robust image feature and invariant to image contrast.

2 METHODS

2.1 Kanade-Lucas-Tomasi method

Kanade-Lucas-Tomasi (KLT) or gradient method (GM) rests on the assumption that image intensity is constant overtime.

Let $g(x,y)$ be the image intensities at pixel coordinates (x,y). The gradient vector of $g(x,y)$ are approximated by partial derivatives

$$\begin{cases} g_x(x,y) = g(x,y) * k_x \\ g_y(x,y) = g(x,y) * k_y \end{cases} \tag{1}$$

where the symbol $*$ denotes convolution, and k_x and k_y are first-derivative operators in the x and y directions, respectively. The covariance matrix of the two patterns g_x and g_y is expressed by

$$G = \begin{bmatrix} \Sigma {g_x}^2 & \Sigma g_x g_y \\ \Sigma g_x g_y & \Sigma {g_y}^2 \end{bmatrix} \tag{2}$$

where Σ indicates the integration area in a local 2-D space. By applying PCA to the matrix, G, we obtain two eigenvalues λ_1 and λ_2 where $\lambda_1 > \lambda_2 \geq 0$. The corner is detected when two eigenvalue satisfy the condition $\lambda_1 \approx \lambda_2 \geq 0$.

2.2 Ando corner detection

The Ando method can categorize the image field into an omni-direction of the gradient. It can detect corner by using Eq. (3)

$$Q_{EG} = \frac{4\left(\Sigma g_x{}^2 \cdot \Sigma g_y{}^2 - \Sigma g_x g_y{}^2\right)}{\left(\Sigma g_x{}^2 + \Sigma g_y{}^2\right)^2 + \sigma_{EG}{}^4} \tag{3}$$

$\sigma_{EG}{}^4$ is needed to force the denominator does not equal to zero. The value of Q_{EG} is varied from 0 to 1. If it equals or closes to 1, the gradients are omni-directional. On the other hand, if it equal to 0, the gradients are uni-directional.

2.3 Harris corner detection

The Harris corner detector is widely used in digital image processing and computer vision. It can detect both edges and corners by using Eq. (4)

$$H = det\begin{bmatrix} \Sigma g_x{}^2 & \Sigma g_x g_y \\ \Sigma g_x g_y & \Sigma g_y{}^2 \end{bmatrix} - k \cdot \left(trace\begin{bmatrix} \Sigma g_x{}^2 & \Sigma g_x g_y \\ \Sigma g_x g_y & \Sigma g_y{}^2 \end{bmatrix}\right)^2 \tag{4}$$

where k is a constant. It is normally in between 0.04 and 0.06 [11]. The value of H presents the cornerness of the region. If the value is positive, the gradients are omni-directional, while if it is negative, the gradients are one-directional.

2.4 The proposed method

We propose the unit gradient vectors (UGVs) in place of conventional features such as image intensities and gradients, because UGVs are known to be insensitive under the varying illumination [8], [9].

The unit gradient vectors are computed by dividing gradient vectors by their magnitudes:

$$\begin{cases} n_x(x,y) = g_x(x,y)/\sqrt{g_x{}^2(x,y) + g_y{}^2(x,y)} \\ n_y(x,y) = g_y(x,y)/\sqrt{g_x{}^2(x,y) + g_y{}^2(x,y)} \end{cases} \tag{5}$$

3 RESULTS AND DISCUSSION

For the qualitative evaluation of the corner detection methods, KLT, Ando, Harris corner detector, and the proposed method, the synthetic images are created by generating an 8-bit gray-scale image of size 120 by 120 pixels. The tested image consists of difference 36 intensities levels. It has 25 different contrast corners which are both high and low contrast patterns. The difference of intensity from the top to the bottom of both rows and columns are set from large to small. Zero-noise Gaussian noise is added to test image to generate a noisy image. The signal to noise ratio, SNR, is 40 dB. The size of the block to search the feature is set at 5 by 5 pixels. We search the feature on every single pixel. The tested image is shown in Fig. 1.

We compare the performance of the conventional methods and the proposed method in a pair. We first compared KLT versus the proposed method as show in Fig. 2(a) and 2(b), respectively. The result is scaled from 0 to 1 to simple visualization. The brighter spot respond to the high cornerness on the test image. KLT is high response to the high contrast pattern, in the upper-left of the image, but almost miss the low contrast pattern, in the lower-right of the image as show in Fig. 2(a). The proposed method is high response to the entire corner pattern as show in Fig. 2(b).

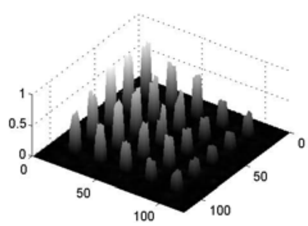
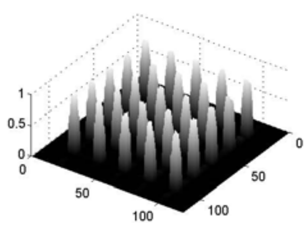
(b)

Fig. 1. (a) A mildly noisy test image. (b) The test image plotted in 3D.



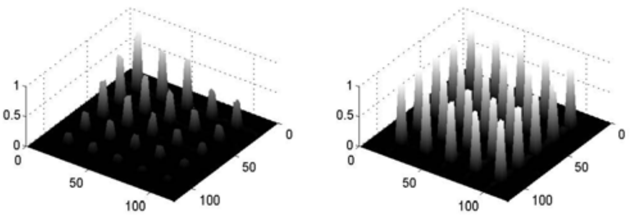
(a)



(b)

Fig. 2. Responses to corners by (a) the KLT method and (b) the proposed method.

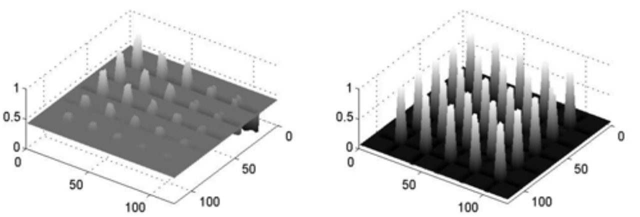
Secondly, we compared the Ando corner detection with the proposed method as show in Fig. 3. The corners are selected by using Ando method with σ = 900 as shown in Fig. 3(a). The proposed method also uses the same value of σ which used in Ando method but proposed method shows the outer performance that has high response on the low contrast area which Ando has low response.



(a) (b)

Fig. 3. Responses to corners by (a) the Ando method, (b) the proposed method.

Next, Harris corner detector is compared with proposed method. The corner is selected by using the Harris corner detector with k = 0.04 as show in Fig. 4(a). Harris can detect both corner and edge in the same time. The white and black pixels respond to the corner and edge, respectively while the gray pixels are shown the flat area. Even it can detect all difference patterns, i.e., corner, edge, and flat area, in the entire image, it almost miss the detection in the low contrast corner. Fig. 4(b) shows the response of the proposed method. It can detect all different patterns especially, also detect the low contrast corner.



(a) (b)

Fig. 4. Responses to corners by (a) the Harris corner detector and (b) the proposed method.

4 CONCLUSION

This paper presents a comparative study between the popular feature detection methods such as KLT, Ando, and Harris corner detectors, and the proposed method. We introduce the unit gradient vectors in place of conventional image information as gradient. We have shown that the proposed method can detect corners regardless of their contrast. This will lead to stable corner detection under difficult conditions such as irregular illuminations and poor lighting.

Abstract: In this paper, we propose a new human detection method based on local descriptors and machine learning. The HOG feature and RealAdaBoost are well-known methods for detecting humans. However, this technique has shown its limitation because of long processing time due to fixed number of weak-classifiers. To overcome this problem, this paper proposes a HOG based framework using multiple-scale cells for the RealAdaBoost with a variable number of weak-classifiers. The proposed method is faster than existent methods, because it describes more comprehensive intensity gradients and classifies them using low dimension feature vectors. Experimental results show that the proposed method is effective in accuracy and processing time.

Keywords: HOG, Multiple Scale Cells, RealAdaBoost, human detection, machine learning.

1. Introduction

Recently, various techniques for human detection (especially pedestrians) from an image have been developed. These techniques are the main topics in the field of ITS (Intelligent Transport systems) and robot vision. For pedestrian detection, there exist many approaches such as background subtraction, motion based techniques [1], etc. that have been proposed. However, these methods have restrictions in the scenes in which they can be used. For example, some methods can be used only for stationary camera images or only for a moving object. Therefore, using local descriptors and machine learning schemes which can respond to a moving camera and do not have restriction in the detection scene has been gaining spotlights. More especially, the Histograms of Oriented Gradients (HOG) feature proposed by Dalal and Triggs [2] is one of the well-known methods for human detection. The method has robustness to illumination and small shape changes.

There exist a lot of methods based on the HOG feature [3, 4]. For example, Nakashima has proposed Multiple-HOG [5]. Multiple-HOG method is based on using a variable number of divisions on the direction of intensity gradients. Better results have been obtained as compared with conventional methods because of its flexible as well as precise description of the gradients in a cell. However, since the size of a cell is fixed, the amount of information included in one feature vector is limited. Moreover, these methods have the same problem, i.e., long processing time, because HOG needs normalization of every block in an image and the number of weak-classifiers is large and fixed in the RealAdaBoost. If the number of weak-classifiers is reduced, processing time can be faster. Instead, we may might lose high accuracy.

In this paper, we propose a novel human detection method employing the HOG feature based on multiple-scale cells for RealAdaBoost with a variable number of weak-classifiers. By this method, since the size of the edges can be captured more comprehensively, one feature vector contains more information. Therefore, this method can perform at higher speed using few weak-classifiers. Experimental results show that the proposed method is effective in accuracy and in processing time.

2. HOG feature based on Multiple-scale cells

When calculating the HOG feature employing the method proposed by Dalal et al., a cell size is fixed. In this method, we can acquire only the information on a small cell (usually 5×5 pixels) as shown in **Fig. 1(a)**. However, a pedestrian has generally large and strong vertical edges. We propose Multiple-scale-cell HOG feature in this paper. The idea of Multiple-scale-cell HOG is illustrated in Fig. 1(b).

(a) (b)

Fig. 1. Arrangement of a cell in the case of (a) HOG, and (b) Multiple-scale-cell HOG.

The Multiple-size-cell HOG has a variable size of cells. For example, 5×5, 5×20, 20×5 and so on. Moreover a cell-overlap is permitted. Then we can describe the size and the location of an edge comprehensively. The cell size is defined as follows.

$$S_x = \alpha n + C, \qquad S_y = \beta k + C \tag{1}$$

Here S_x is the cell size in the horizontal axis direction, and S_y is the cell size in the vertical direction.

When calculating the HOG feature, block normalization consumes a large part of the processing time, although it assures robustness to lighting condition change. Therefore normalization with every block is not performed in the proposed method. As a substitute, cell overlap is permitted which leads to the use of a larger number of cells.

3. RealAdaBoost with variable number of weak-classifiers

Boosting obtains classifiers of good performance (a strong classifier) by combining many weak-classifiers. The number of weak-classifiers is related to accuracy and processing time. In this paper, we also propose a technique for making the number of weak-classifiers variable. If an image is simple enough to recognize it, such as a road or the sky, we use a small number of weak-classifiers. On the other hand, if an image is complicated, such as roadside trees, we use a large number of weak-classifiers.

First, we train provided data using RealAdaBoost. In RealAdaBoost, the output of a weak-classifier becomes large (positive) when it is a positive sample, and it becomes small (negative) when the sample represents the negative class. Using this characterization during the learning stage of RealAdaBoost, the threshold value is determined by the following formula.

$$th_i = \min\{h_{i,1}, h_{i,2}, \cdots h_{i,N_p}\} \tag{2}$$

Here *i* is the round number, th_i is the threshold in round, h_i is the output value of a weak-classifier in *i* round about a positive sample. N_p is the number of positive samples.

Discrimination is performed using the computed threshold value. The idea of discrimination is illustrated in **Fig. 2**. In Fig. 2, WC_i are weak-classifiers in round i. Even if i have not reached, if the output of weak-classifiers is smaller than a threshold value, calculation will stop at the time. During the image search of a human, the number of weak-classifiers is made variable for every search window as shown in **Fig. 3**.

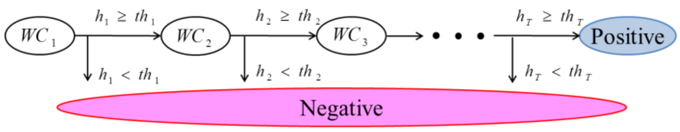

Fig. 2. Variable number of weak-classifiers.

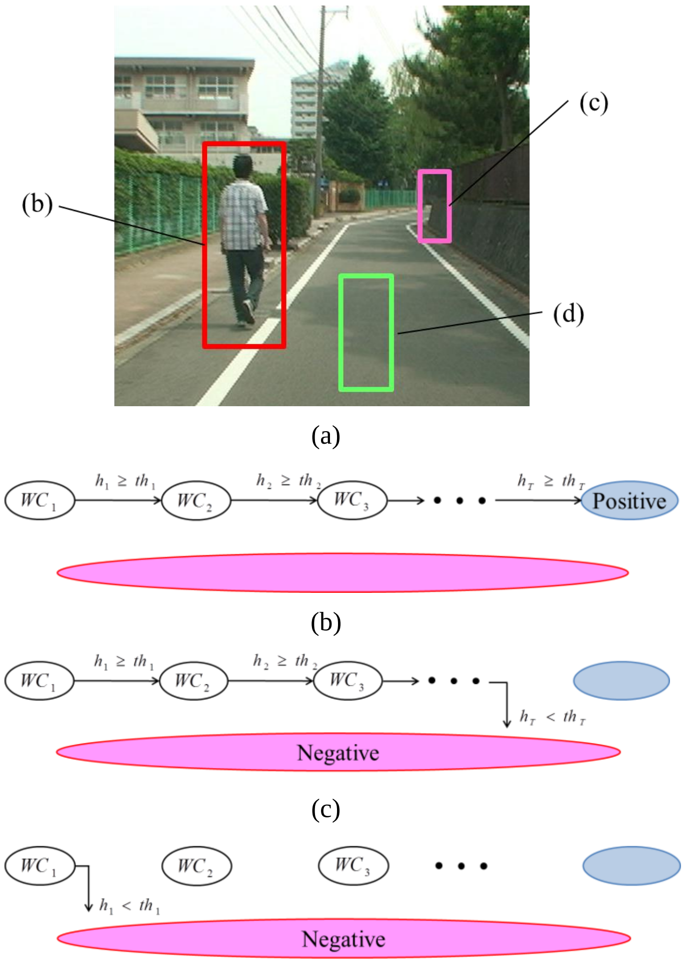

(d)

Fig. 3. The number of weak-classifiers for every search: (a) Input image, (b) positive class, (c) difficult negative class, and (d) easy negative class.

4 EXPERIMENTAL RESULTS

We evaluated the proposed method for human detection by using INRIA Person Dataset. Training data contains 2416/6000(positive/negative) images and test data includes 1126/3000(positive/negative) images. The image size is 30×60 pixels. We compared the proposed method with the conventional method using the HOG feature [1] and RealAdaBoost, and using the Multiple-HOG feature[5] and RealAdaBoost.

The combination of the method in the experiment is shown in a **Table 1**. We compared two previous methods to our proposed schemes. In [1], [5] and our proposed method-1, the number of weak-classifiers is 500. First, the accuracy evaluation experiment of the proposed method (Multiple-scale-cell HOG) was conducted. The DET curve is shown in **Fig. 4**. The DET curve is plotted: True Negative rate is the vertical axis, whereas False Positive rate is the horizontal axis. The method that has its plot in the lowest and the left most area is considered to be the best. Moreover, the accuracy in the case of 500 weak-classifiers is shown in **Table 2**.

Next, we conducted the evaluation experiment of RealAdaBoost with variable number of weak-classifiers. The relationship between the number of weak-classifiers and the rate of an error is shown in **Fig. 5**. The vertical axis represents the error rate. The method that has the lowest plot is the best, which the proposed method-2.

Finally, processing time is compared in **Table 3**. Since processing time differs in a Positive class and a Negative class sample, in the proposed method-2 the processing time of each class is shown separately.

Table 1. The combination of the method in

previous method-1[1]	HOG and RealAdaBoost

previous method-2	40.24	
proposed method-1	28.96	
proposed method-2	27.80	0.99

5 DISCUSSION

Fig.4. shows that the proposed method achieved satisfactory accuracy compared with the previous methods. Table 2 also supports this fact. Moreover, the best accuracy was obtained by using Multiple-scale-cell HOG and RealAdaBoost with variable number of weak-classifiers from as shown in Fig.5. It is thought that a satisfactory result is obtained because the probability of FPR was reduced by making the number of weak-classifiers variable.

Moreover, Table 3 showed that the proposed method-2 performed the specified task at a higher speed. This is due to the skipping of the block normalization during the feature vector computation stage. Moreover, during the discrimination stage, it turns out that the negative class can be eliminated at a high speed.

Next, the plot showing the relationship between the number of weak-classifiers and the rate of an error in the first 100 rounds is shown **in Fig. 6**. As shown in Fig. 5, When the number of weak-classifiers is high (~500), the difference in the accuracy of previous methods and Multiple-scale-cell HOG (proposed method-1) is small. However, as shown in Fig. 6, in the first 100 rounds, there is a big difference in the accuracy of two methods. For this reason, within the first 100 rounds, the proposed method can eliminate the negative class samples with high accuracy. This is considered to be based on the contribution of a large scale cell. The amount of information which one feature vector has by using a large scale cell becomes large. Therefore, good accuracy can be acquired when few weak classifiers are used. This is understood also from the feature selection process. The selected edge in three first rounds is shown in **Fig. 7**. It turns out that a large edge is chosen in the first 100 rounds. On the contrary, when the number of weak-classifiers is high, a small edge is chosen. That is, first, its attention is paid to big edge and easy portions, such as a road domain, are eliminated. Next, as Round becomes high, difficult objects, such as a roadside tree, are eliminated using small edge.

6 CONCLUSIONS

We have proposed a method of human detection employing the Multiple-scale-cell HOG and RealAdaBoost with variable number of weak classifiers.

In the experiment, it was checked that it performed higher-speed processing and a better precision than the previous methods. Performance of the method was satisfactory. We are going to apply the method to ITS and robot vision.

Abstract: We propose an accelerated approach of gesture recognition, "Early Recognition". Early recognition is a method to make a decision of human gesture at their beginning part of it. A gesture consists of a sequential postures. In the training phase, a lot of postures which make the gestures are trained by Self-Organizing Map (SOM). Then, representative postures on the SOM are investigated their contribution ratios for each gesture. Besides, the representative postures are registered into a hash table to realize quick search of a posture in the test phase. When an input gesture is given, a posture in each frame is used as a query and the most similar posture is found from the training samples. Then, if the contribution ratio for a certain gesture exceeds a predefined threshold, the system outputs the gesture label as the recognition result. Through our experiments, we found out that the proposed method outperformed the traditional method in terms of the computational cost and the response speed until the result was determined. Besides, the recognition accuracy of the proposed method was almost the same as the traditional one.

Keywords: Early Recognition, Locality-Sensitive Hashing, Self-Organizing Map

1 INTRODUCTION

Recognizing human gestures plays an important role to realize a man-machine interactive system. We tackle the problem of realizing a seamless interaction required video action game consoles, robotics, remote controller, etc. Generally, a system recognizes a human gesture after the gesture has completely finished. Therefore, if the length of the gesture is long, a user has to wait for the response until the recognition process finishes. That's why general system occurs a large time lag, and loses the smoothness.

In recent years, a new methodology of gesture recognition called "early recognition" has been proposed[1][2]. Early recognition is the method that system determines the recognition result before user's gesture has finished. It gives us very useful solution for the problem of delay of interaction. In the previous approach[3], Self-Organizing Map (SOM)[4][5] is utilized for making a codebook of representative postures from training samples, then contribution ratio of each representative posture is estimated for each gesture class. In recognition process, the best matched representative posture is found from the codebook by searching all nodes of SOM. Therefore, the larger the number of nodes becomes, the longer time search phase takes. Furthermore, if searching takes longer time than a frame rate of input, a system will drop several frames, that may result in lower performance of recognition speed. Generally, the performance depends on the number of nodes, but it requires a large computational cost to find a best matched one.

In this paper, we propose the accelerated approach for searching the best matched node by using Locality-Sensitive Hashing (LSH)[6], in which the computational time does not depend on the size of code book. In the following this paper, we will give a detailed explanation about the proposed method. Besides, the effectiveness of the proposed method becomes clear through the experimental results.

2 PROCESSING FLOW OF PROPOSED METHOD

Proposed method is divided into two processes; training process and recognition process.

2.1 Training Phase

Training process is divided into three steps. Step1 and Step2 are inspired from the previous work by Kawashima *et al*[3]. Flow of this process is explained as follows,

Step 1 Training of Representative Postures

Step 2 Calculation of Contribution Ratio

Step 3 Registration to Hash Table

First, the training sample is clustered by SOM and center vector of each cluster, which is called "representative posture" is output to each neuron of SOM. Secondly, "contribution ratio", which shows how often each representative posture is used for each gesture class is calculated. Finally, sets of representative postures and contribution ratio are registered to hash table. In following subsection, we explain each step in detail.

Step 1 *Training of Representative Postures*

The posture data, which are the skeleton data (Fig.1) sequences of human posture from Microsoft Kinect SDK, are collected as training samples. Each skeleton data has 20 observation points and each observation point

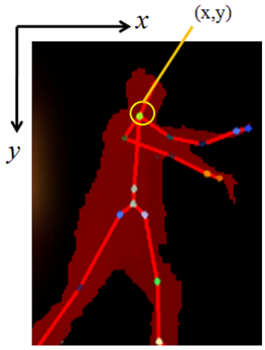

Fig. 1. Skeleton data

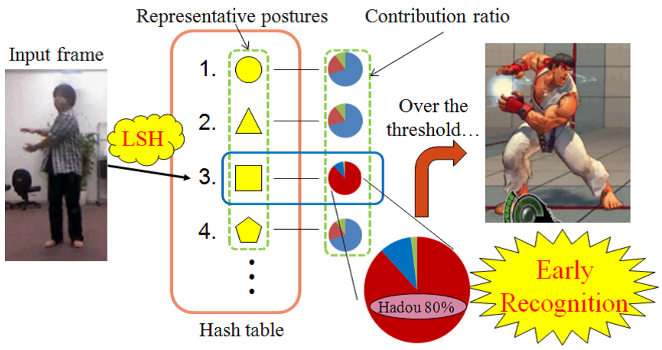

Fig. 2. Flow of Recognition Phase

has 2 dims (x, y) information, so each frame data has 40 dims vectors as information of posture (1 frame = 1/30 sec). Then, that samples of motion's template postures are clustered by SOM and a output center vector of each cluster, which called "representative posture", are registered to each neuron of SOM.

Step 2 *Calculation of Contribution Ratio*

"Contribution Ratio" denotes how often a representative posture is used for each gesture class. The template postures of each motion are input to SOM again and we count the number of times which shows how often the neurons of SOM are used for each gesture class. Then, the ratio of that number of one motion to that of all motions is treated as contribution ratio. In short, The higher value it becomes in only one motion, the more peculiar the posture is to the motion. That ratio is also registered to SOM with each representative posture. Then, the representative posture and the contribution ratio of that are linked by a label number.

Step 3 *Registration to Hash Table*

The representative postures registered to neurons of SOM are registered to hash table. The parameter l and k (Sec.3) need to be selected the proper values because this values are directly relative to the recognition accuracy.

2.2 Recognition Phase

Flow of the recognition phase is shown by Fig.2. The recognition phase is performed frame by frame. In each frame, a best matched posture is searched from all registered representative postures in hash table. If a matched posture is found, its corresponding contribution ratio for each gesture is examined. If a contribution ratio of a certain gesture is higher than a predefined threshold, the system makes final decision of gesture recognition. In other words, the gesture label is the recognition result.

The previous method requires $O(n)$ (n is the number of representative postures) operations to find the best matched posture because of a greedy algorithm. When the n increases, the calculation cost also increases explosively. It is not desirable from the viewpoint of early recognition. Meanwhile, the operation cost of a hash-based approach is not affected by the number of samples. LSH requires $O(kl)$ operations. The values of the k and l are very smaller than n. Moreover, it guarantees a constant operation cost even if the number of postures increases. The search method of LSH is explained in Sec.3.

3 LOCALITY-SENSITIVE HASHING (LSH)

Locality-Sensitive Hashing (LSH) is a kind of approximate nearest neighbor search. Nearest neighbor search needs to calculating distance from query data point to each data point and it takes an enormous amount of time. However, "approximate" nearest neighbor search is the way of finding slate points which are near from query data point. This way can reduce much calculating time because of not requiring to calculate distance between each data points and query data point.

This search method uses "locality-sensitive" hash function. It is the function that the nearer the distance from query data to a data point, the higher value the probability that hash values of both data are matched takes. This function is defined by,

$$h(\boldsymbol{p}) = \left\lfloor \frac{\boldsymbol{a} \cdot \boldsymbol{p} + b}{w} \right\rfloor \tag{1}$$

$\boldsymbol{a}$ is the vector whose value of each element is obtained independently by Gaussian distribution. $\boldsymbol{p}$ is query data, and w is width of hash, b is the real number which is selected in an interval $[0, w]$.

In making search table phase, the k function $g =< h_1, \cdots, h_k >$ is applied for all data points, and the product set of each function's result is obtained. Furthermore, The l group of function $\{g_1, \cdots, g_l\}$ is also applied, and the search table is constructed.

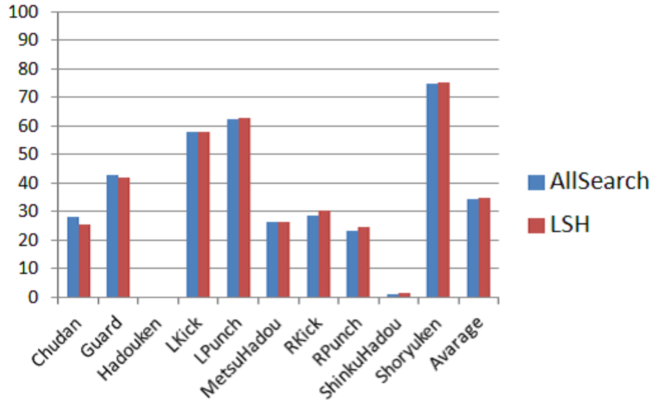

Fig. 3. Recognition Accuracy of 10×10 SOM[%]

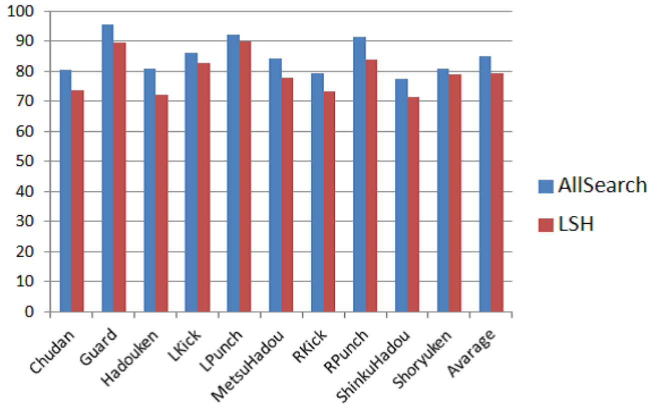

Fig. 4. Recognition Accuracy of 100×100 SOM[%]

In searching phase, when the query vector p is input, the hash value of this vector is calculated and matched product set is searched on each table. Then, the sum of sets of each search result is output as nearest neighbor slate points.

4 EXPERIMENTS

4.1 Preparation

We used the video game software "STREET FIGHTER 4" as the theme of early recognition. Ten kinds of gestures were selected for the experiment. The Kinect sensor captured each gesture at 30fps, which consists of 40-dimensional feature vector (2-dimensional position × 20 points) in each frame. Eight examinees played each gesture 30 times. Therefore, totally 2,400 (30×10×8) samples were collected. These samples were used for 6-fold cross validation in the following evaluation.

The parameters of LSH were set to k =64 and l =5. The size of SOM was changed as 10×10 and 100×100. The threshold to determine the recognition result was set to be 0.6. In other words, if the contribution ratio of the best matched posture exceeded the threshold, the system output

Table 1. Computational Time (sec)

100×100	0.000059	0.1031

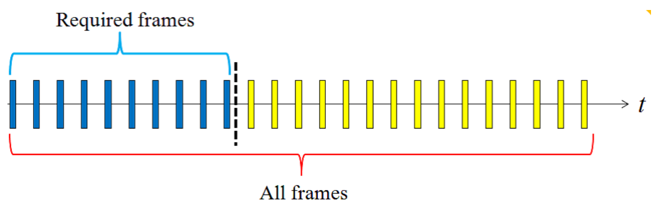

Fig. 5. Definition of Frame Ratio for Recognition (FRR)

the recognition result. In the test phase, if the computational time of each frame exceeded the video rate (i.e. 0.033sec), several frames were skipped (not processed) according to the time. For example, if it took about 0.066sec for each frame, every two frames were used for the evaluation.

4.2 Results

4.2.1 Computational Cost

Table 1 shows the average computational time for finding the best matched posture. In the case of greedy search (all search in the table), the computational time is proportional to the number of neurons. Therefore, the 100×100 size of SOM took about 100 times longer than the 10×10 size of SOM. If we use the 100×100 size of SOM, it will take about 0.1 sec (work at about 10fps). Therefore, every three frames will be used in the online recognition process.

On the other hand, LSH took about 0.00004∼0.00006 sec for each frame, and the computational time was almost constant even if the number of neurons increased. Therefore, we need not skip any frame if the LSH is used for searching the best matched posture.

4.2.2 Accuracy

The recognition accuracy is shown in Fig. 3 and Fig. 4. The horizontal axis shows the label of each gesture and most right is the average of all gestures. The vertical axis means the recognition ratio. We compared two approaches; a greedy search and a LSH-based search. In Fig. 3, the 10×10 size of SOM was used. As discussed above, the computational time was less than 0.033 sec so that any frame was not skipped, but the recognition accuracy was very low for several gesture classes. It makes no sense to reduce the computational time since it results in low accuracy of recognition result.

On the other hand, when the SOM had 100×100 neurons, every three frames were used in the greedy search. The ac-

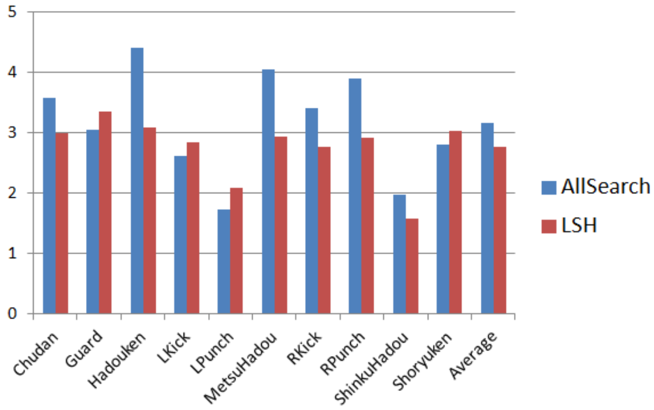

Fig. 6. Frame Ratio for Recognition [%]

curacy of both methods was almost the same. Strictly speaking, however, the accuracy of the greedy search was slightly more than the one of LSH even though the greedy search skipped several frames. We guess the reason as follows. The LSH-based search provides an approximate nearest neighbor search result. Therefore, the found posture is not always the best matched one, and if such a posture unfortunately has a high contribution ratio for a wrong gesture, a wrong label will be output from the system.

4.2.3 Response Speed

One of the most important evaluations is to measure the response speed of the system. In other words, how early the system could output the correct recognition result is evaluated. To measure the response speed, we define the frame ratio for recognition (FRR) as follows.

$$FRR = \frac{\text{\# of required frames}}{\text{\# of all frames}} \times 100 \qquad (2)$$

Fig. 5 supports the explanation of FRR. The FRR evaluates the percentage of the number of frames which are used for recognition to the all frames. Therefore, the smaller value of the FRR is desirable. The evaluation was performed when the system output the correct label only.

Fig. 6 shows the evaluation result of FRR. The FRR of LSH-based method was totally lower than the one of the greedy method. The greedy method skipped several frames in the online recognition process because of its computational time. That's why the FRR becomes higher than LSH-based method, which could investigate all of the input frames.

4.3 Discussion

Through the above experimental results, we found out some advantages of the proposed method. Firstly, the recognition accuracy of the proposed method did not become lower even it reduced the computational cost. Secondly, the response speed was faster than the traditional approach. Therefore, the proposed method realizes two important issues; high accuracy and quick response for input gesture patterns. Finally, the proposed method will work well even if the number of gesture classes increases since the computational cost is independent of the samples.

5 CONCLUSION

We have proposed an accelerated approach of early recognition of human gestures. Self-Organizing Map (SOM) is utilized for learning human gestures and obtaining the representative postures. When we investigate the postures which is the most similar to input posture, if searching all nodes of SOM in previous method is conducted, the computational cost becomes larger in proportion to the number of the representative postures. Moreover, if this phase takes longer time than a frame rate of input, the searching will drop the several frames and give bad effect on the result of recognition. Therefore, we used the Locality-Sensitive Hashing (LSH), which is a kind of approximate nearest neighbor searching, instead of previous method. Through the experiments, we could prove that the accuracy could be kept with much lower computational cost than the previous method. We are now researching the recognition which used the weighting to postures data to improve the recognition accuracy.

Abstract: In this paper, we present a computational model for source recognition in acoustic sensor arrays. The proposed model uses a hybrid method of neural networks to create symbols then hidden Markov models that collectively learn to discriminate sequences of symbols from a collection of recordings from bird species with minimum human intervention. Preliminary simulation results indicate that this model is capable of producing acceptable levels of classification performance.

Keywords: Acoustic sensor arrays, hidden Markov models, bird species classification

1 INTRODUCTION

Over the last few years, we have been engaged in a research program that aims at understanding the capabilities and limitations of sensor arrays in habitat monitoring applications [1]. Particularly, we have developed acoustic sensor arrays for monitoring the diversity and behavior of bird species at several locations in Mexico and in the US. More recently, our research program has evolved towards the application of this technology for understanding the structure and function of bird song.

As part of this study, we have focused on developing robust filters that are able to discriminate bird species, and in some cases, bird individuals with reasonably high accuracy. Specifically, we have explored the use of unsupervised learning methods such as self-organizing maps [11][13], and supervised learning methods such as support vector machines [12], among others. We have had success with the use of hidden Markov models (HMMs) for this problem [9].

We believe that given the appropriate conditions, an array of sensors should be able to self-organize so as to behave as a single ensemble [4][8]. In this idealization, sensors can identify and collectively learn to classify events of interest from an arbitrary acoustic recording stream, with minimal human intervention. This ability is at the core of what is required for achieving adaptive behavior and communication in sensor arrays.

Towards this end, we developed a computational model for source recognition in acoustic sensor arrays. The proposed model uses hidden Markov models that self-organize to discriminate a collection of input sequences with minimal human intervention. We chose HMMs for its ability to discriminate input sequences of arbitrary length, which have proven difficult for alternative classification methods.

Particularly, we introduce a collective learning algorithm that enable a collection of HMMs to learn to classify four different species of antbirds. In the collective learning procedure, a sensor detects an input sequence from the input stream and uses its HMM to determine its corresponding output. The sensor output is then combined with those of its neighbor sensors to produce a consensus output. The sensor then computes the maximum likelihood estimators from these consensus sequences to update its parameters, and the learning process continues.

The overall objective of this self-organizing learning process is to enable HMMs to accurately classify the input sequences and to converge to consistent collective classifications along the array. We used recordings obtained from our field studies in a tropical rainforest in Chiapas, Mexico. From these recordings, we constructed a collection of training sets consisting of tokenized sequences of bird songs.

2 METHODS

2.1 Self-organizing HMMs

In the proposed model, the classification of bird species is produced by hidden Markov models (HMMs). HMMs are extensions of Markov chains in which an observation is a probabilistic function of the state [7].

Formally, a *hidden Markov model* is a 4-tuple (Q, Σ, A, E), where

1. Q is a finite set of states,
2. Σ is an alphabet of symbols,
3. $A = (a_{kl})$ is a $|Q| \times |Q|$ matrix of state transition probabilities,
4. $E = (e_k(b))$ is a $|Q| \times |\Sigma|$ matrix of emission probabilities

Let $M = (Q, \Sigma, A, E)$ be a hidden Markov model. A path $\pi = \pi_1 \ldots \pi_n$ is a sequence of states. The probability that a sequence x of symbols from the alphabet Σ was generated by the path π is

$$P(x|\pi) = \prod_{t=1}^{n} P(x_i|\pi_i)P(\pi_i|\pi_{i+1}) = \prod_{i=1}^{n} e_{\pi_i}(x_i) \cdot a_{\pi_i,\pi_{i+1}}$$

The decoding problem is formulated as to find the optimal path $\pi^* = \arg\max_\pi P(x|\pi)$ for x such that $P(x|\pi)$ is maximized.

The solution of the decoding problem is provided by the Viterbi algorithm [7]. The idea is that the optimal path for the $(i+1)$ prefix $x_1 \ldots x_{i+1}$ of x uses a path for an i-prefix of x that is optimal among the paths ending in an unknown state $\pi_i = k \in Q$.

Define $s_k(i)$ as the probability of the most probable path for the prefix $x_1 \ldots x_i$ that ends with state k ($k \in Q$ and $1 \le i \le n$). Then

$$s_l(i+1) = e_l(x_{i+1}) \cdot \max_{k \in Q}\{s_k \cdot a_{kl}\}$$

Let $M = (Q, \Sigma, A, E)$ be a hidden Markov model and $x = x_1 \cdots x_n$ be a string over the alphabet Σ. The HMM M produces the output o in response to input x, $M(x) = o$, if a sequence of states $\pi = \pi_0 \ldots \pi_n$ exists in Q with the following conditions:

1. π is the optimal path π^* given the sequence x and the hidden Markov model M, and
2. $\pi_i^* = o_i$ ($1 \le i \le n$) is the state of the optimal path π^* given the sequence x and the hidden Markov model M.

2.2 Learning algorithm

For this study, we devised a collective learning algorithm for HMMs. The model comprises a collection of randomly generated HMMs. For each input in the training set, an HMM uses the consensus optimal path of the HMMs in its neighborhood as its target output. The consensus optimal path is obtained from the neighbor HMMs by voting. The maximum likelihood estimators are then computed from the set of target outputs as follows. We count the number of times each particular transition or emission is used in the set of training inputs. Let these be A_{kl} and $E_k(b)$. Then the maximum likelihood estimators for a_{kl} and $e_k(b)$ are given by:

$$a_{kl} = \frac{A_{kl}}{\sum_{l'} A_{kl'}}$$

and

$$e_k(b) = \frac{E_k(b)}{\sum_{b'} E_k(b')}$$

The learning algorithm is described in Table 1.

Table 1. Learning algorithm.

2.3 Data set

The samples used in the experiments presented here were provided to us by Martin L. Cody. The dataset consists of songs from four different antbird species that are abundant at the Montes Azules Biosphere Reserve in Chiapas, Mexico. They are listed on Table 2.

The preparation of data proceeded as follows. The songs were segmented using the Raven bird song analysis program [3]. Syllables were identified by small discontinuities in the corresponding spectrogram. Using this procedure, we obtained a collection a syllable samples as listed in Table 3. For each sample, we obtained a series of temporal and spectral measurements using Raven. These parameters were extracted from the sound signal using the short-time Fourier transform (STFT) and selected according to previous studies on bird species classification [3] [6]. These measurements are described in Table 4.

A normalization process was applied to this data because the selected measurements span different orders of magnitude. Such differences might result from how close the subject is to the recorder, for example. Using the mean and the standard deviation of each measurement, we obtained a collection of feature vectors described as z-scores.

The collection of feature vectors describing syllables were classified using a simple competitive learning neural network [5]. Once the syllables have been categorized we proceeded to represent the original songs as strings of symbols using the label from each syllable category. Table 5 shows the string representation of a subset of the songs obtained us-

ing a two-unit competitive learning network, with learning constant $\eta = 0.1$ and epochs = 1000.

Similarly, table 6 shows the string representation of a subset of the songs obtained using a four-unit competitive learning network, with learning constant $\eta = 0.1$ and epochs = 1000.

3 EXPERIMENT AND RESULTS

Multiple simulations were conducted using different combinations of parameter values presented in table 7. The following were the major results:

1. HMMs produced a reasonably good categorization performance ($\sim 82\%$) of the training sets.
2. Acceptable numbers of training steps (~ 100) were required for the collection of HMMs to converge to consistent classifications.
3. The description of bird songs using fewer distinct syllables and HMMs with fewer states produced better classification performance.

To calculate the classification performance we obtain the consensus output sequence from all of the samples in the same category. Then we compute the pairwise similarity of each output sequence produced for each sample in the category with respect to the consensus output sequence of the category.

Table 8 shows the accuracy of classification obtained for the two-syllable experiment using HMMs with 8 states and 100 simulation steps.

Similarly, Table 9 shows the accuracy in classification obtained for the four-syllable experiment using HMMs with 16 states and 200 simulation steps.

4 CONCLUSION

Despite its preliminary character, the results shown here seem to indicate that acceptable categorization of bird species can emerge using self-organizing HMMs. The results also show that the accuracy in classification depends on the number of syllables describing the bird songs. This sug-

gests the existence of a number that is optimum for accurate species classification. Moreover, categorization requires minimum human intervention in contrast with supervised learning methods. In general, experimental results showed that there is an advantage for simulations in which hidden Markov models posses fewer states.

We think the proposed method could be extended in several ways. For instance, the most relevant in practice would be to use this model for event detection and to identify the species that are sharing the acoustic space, in both the temporal and spectral spaces. This capabilities would enable the technology of sensor arrays to explore important questions in ecology regarding both the inter- and intra- species interaction of birds.

It should be noted that the proposed model has only been tested in a simple simulated setting. We will test the proposed model in real settings in the near future. We believe that self-organizing HMMs hold much promise to contribute for the development of fully automated sensor arrays for habitat monitoring applications.

Abstract: This paper proposes a technique for recognizing Japanese Finger-spelling using a sign language user's chest-mounted camera. Unlike existent systems, the technique employs a sign language user's chest-mounted camera attached to the sign language user himself and recognizes his/her sign language through the captured images of Japanese Finger-spelling. We use a silhouette picture of a hand, and MHI (Motion History Image) for Japanese finger-spelling recognition. The recognition method uses the eigenspace method. Furthermore, in order to recognize Japanese finger-spelling from an animation (image sequence), a character segmentation technique is also proposed. Finally, finger characters are recognized and the performance is shown experimentally.

Keywords: Sign language recognition, Chest-mounted camera, Motion history images, Eigenspace method.

1. INTRODUCTION

Recently, requests on computer-based welfare assistance systems have been increasing. In order to develop these systems, a great number of researches aim the development of automatic Japanese sign language recognition systems using image processing. However, conventional recognition systems deal with those input images obtained from a camera facing a disabled person in hearing and speaking [1] or using many sensors [2, 3]. But, normally, we do not possess this kind of system including a camera in our daily life, since it is hardly the case that we happen to meet such disabled people who wish to talk to us. Thus this kind of system would not spread for practical use in our daily life. On the contrary, if a Japanese sign language user is equipped with such a system, it will definitely improve his/her quality of life (QOL), as he/she can communicate to everyone to whom he/she wishes to do so.

In this paper, we propose a system that is held by a sign language user for recognizing his/her sign language. Unlike existent systems, the proposed system employs a chest-mounted camera shown in **Fig. 1** which is held by a sign language user and recognizes his/her Japanese finger-spelling as shown in **Fig. 2** through the captured images of his/her finger shapes. We think this system can be employed as a new human interface for not only Japanese sign language users but also healthy persons.

2. PROPOSED METHOD

In the first step, we extract a hand area from an image taken from a chest-mounted camera. Next, we recognize the Japanese finger-spelling performed by the user employing the extracted hand area as shown in **Fig. 3**.

Fig. 1. Location of the chest-mounted camera

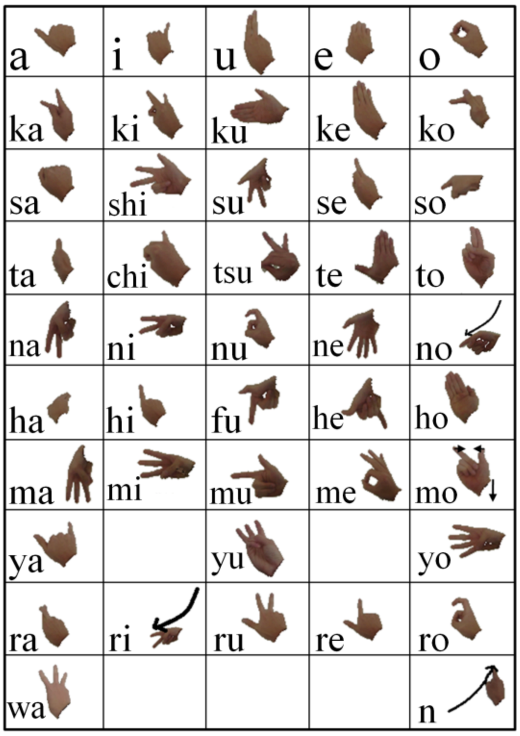

Fig. 2. Japanese finger-spelling list

(a) (b)

Fig. 3. Skin color extraction:
(a) Input image, (b) extracted hand.

2.1 Character recognition

Recognition methods for Japanese finger-spelling are usually composed of a nearest neighbor search in the eigenspace using a hand silhouette for non-moving finger-spelling and nearest neighbor search in eigenspace using a Motion History Image (MHI) [4] and hand silhouettes for moving finger-spelling.

MHI is defined by the following formula.

$$H_\tau(x,y,t)=\begin{cases}\tau & \text{if } D(x,y,t)=1\\ \max(0,H_\tau(x,y,t-1)-1) & \text{otherwise}\end{cases} \quad (1)$$

Here x is the abscissa of an image, y is the ordinate of the image, t expresses time, and τ is a parameter which adjusts time that has passed in the sequence. An example of the expression of a sign language letter by a MHI is shown in **Fig. 4**. Examples of the images used for recognition is shown as well in **Fig. 5**.

Based on this strategy, the recognition of a finger character can be performed regardless of whether motion exists or not.

2.2 Character segmentation

Finger character segmentation in an image sequence is also performed by considering inter-frame difference using hand silhouette images. When the number of moving pixels in the inter-frame difference exceeds a threshold value of motion (Th_M), it is recognized as the frame in which the hand has moved, and when the number of pixels does not exceed the threshold value, it is recognized as the frame which has a stopped (static) hand, i.e., the frame which shows the finger character.

This finger character representation frame is counted. If the number of the frames exceed the threshold value (Th_F), the finger character is recognized as that without a motion. Otherwise it is recognized as that with a motion.

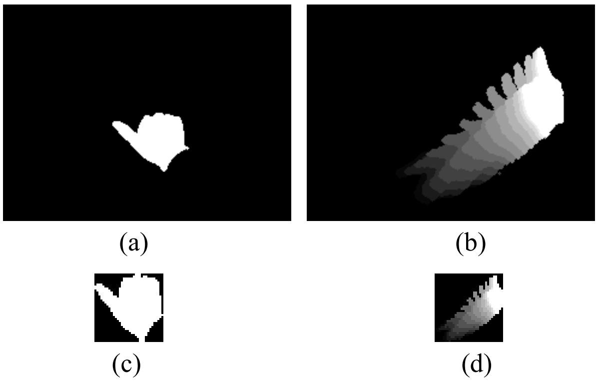

Fig. 5. Examples of database images: (a) Hand silhouette image "a", (b) MHI and hand silhouette image "n", (c) database image "a", (d) database image "n".

3. EXPERIMENTAL RESULTS

3.1 Experiment of Japanese finger-spelling recognition

In the first place, in order to perform the experiment on Japanese finger-spelling recognition, we took the videos of 45 Japanese finger-spelling characters five times. We used four sets for learning, and one set for recognition. This process was repeated five times for one person, and it was repeated with respect to five persons. The recognition rate is computed from the following formula.

$$Recognition\ rate=\frac{CR}{ALL} \quad (2)$$

Here CR is the number of correctly recognized characters, whereas ALL is the number of all characters.

Finally the proposed method achieved 89.1% (1002/1125) of the recognition rate. A detailed result is shown in **Table 1** and **Fig. 6**.

It is thought that incorrect recognition arose in the characters in which the shape or motion are similar with each other, e.g. "no" and "ri". It is shown in **Fig. 7**.

Table 1. Individual recognition rates

	Person A	Person B	Person C	Person D	Person E
Data 1	91.1%	93.3%	75.6%	88.9%	82.2%
Data 2	95.6%	84.4%	91.1%	82.2%	88.9%
Data 3	95.6%	93.3%	88.9%	86.7%	77.8%
Data 4	100.0%	95.6%	95.6%	84.4%	86.7%
Data 5	86.7%	93.3%	91.1%	84.4%	93.3%
Average	93.8%	92.0%	88.4%	85.3%	85.8%

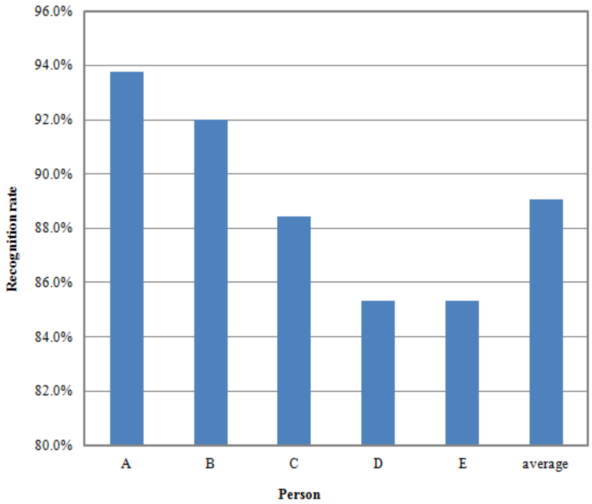

Fig. 6. Average recognition rates of five persons.

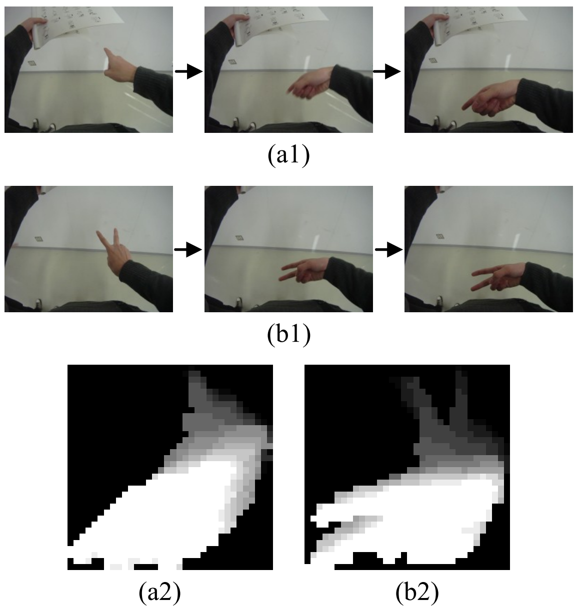

Fig. 7. Examples of similar character:(a1) Input images "no", (b1) input images "ri", (a2) database image "no", (b2) database image "ri".

3.2. Experiment of character segmentation

In the second place, we performed the experiment on character segmentation. We took videos of 6 sentences using Japanese finger-spelling characters four times.
They are 'kon-nichiwa', 'ohayo', 'kore ikura', 'itsu kitano' and 'toki wa kanenari'. An evaluation method is described in the following.

First, the correct answer key-frame which should certainly be contained is set to the character representation section by manual for every character of a text. When the correct answer key-frame is contained in the detected character representation section, it is considered as success (TP: True Positive), and when more than one are contained with the case where it is not contained, it is considered as failure (FP: False Positive). Moreover, the finger character accompanied by a motion or a finger character without a motion is distinguished among success (TP), and success is defined as R (Right). It evaluates using right display rate ($success$) and distinction rate ($decision$). The following formula defines $success$ and $decision$.

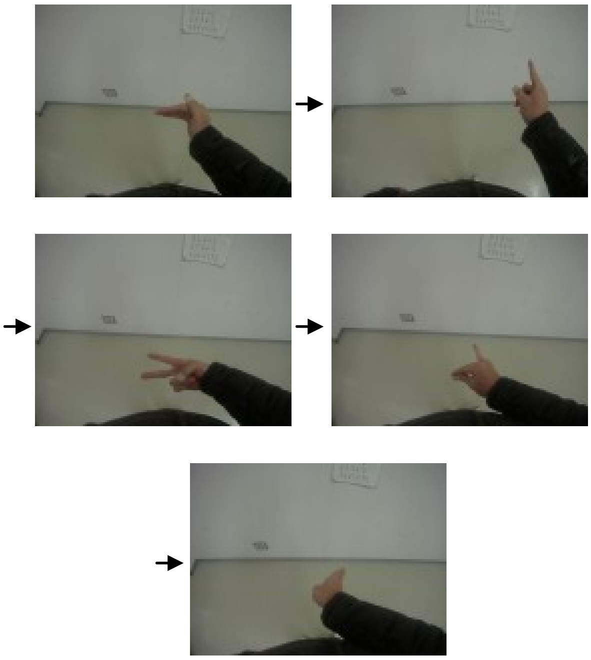
$$success = \frac{TP}{NUM} \tag{3}$$

$$decision = \frac{R}{TP} \tag{4}$$

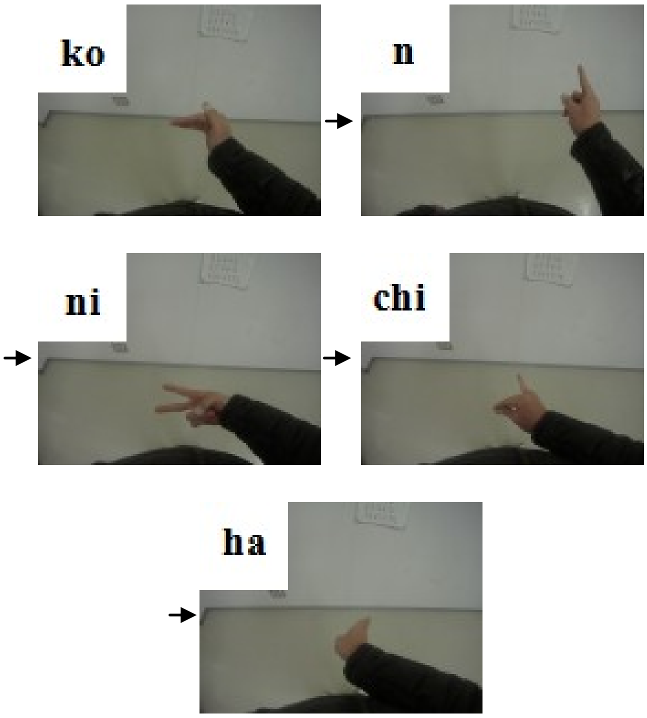
Here NUM is the number of characters in a text.

The proposed method segmented the sentences at a rate of 90.8% ($success$). Among these, 77.8% of the letters were correctly recognized concerning the presence or absence of movement ($decision$).

Since the time to display a character differs from person to person, the existence of a motion in a character has become less discriminative feature. Also, since the motion was distinguished using the number of change pixels, it is thought that the size of the hand being reflected has caused errors. The result of the text recognition using both Japanese finger-spelling recognition method and character segmentation method is shown in **Fig. 8**.



(a)



(b)

Fig. 8. The recognition result of "kon-nichiwa": (a) Part of input animation, (b) part of output animation.

4. CONCLUSIONS

We proposed a Japanese finger-spelling recognition method from the chest-mounted camera images of a Japanese sign language user. The performance of the method was satisfactory. However, there still exists a problem in the accuracy of character segmentation. As future work, we are going to improve the character segmentation method. Application to real time recognition is planned and a voice sound and P-sound recognition method will be investigated as well.

Abstract: This paper presents the MEMS (Micro Electro Mechanical Systems) micro robot using piezoelectric actuator mechanisms. The size of the fabricated micro robot was 3.8, 4.0, 3.5mm, width, length and height, respectively. The basic components of the MEMS micro robot were made from silicon wafer. The micro fabrication of the silicon wafer was done by the MEMS technology. The vibration of the piezoelectric elements was transduced to rotational movement by the piezoelectric actuator mechanisms. Link mechanisms generated the locomotion of the robot from rotational movement. In this paper, continuous movement was achieved by using the piezoelectric actuator mechanism without thermal activation.

Keywords: MEMS, Micro Robot, Piezoelectric Elements.

1 INTRODUCTION

Many studies have been done on micro robots for several applications such as precise manipulations, medical fields, and so on [1, 2]. Although the miniaturization of the robot has been mainly progressed by mechanical machining and assembles, some difficulty has appeared in order to achieve further miniaturization. However, mechanical machining is difficult to fabricate the component which is smaller than 1mm size. Therefore, MEMS (Micro Electro Mechanical Systems) technology which is the micro fabrication technology based on the IC production line has been studied for fabricating the components of the micro robot [3, 4].

We are studying about the micro robot system for the purpose of construct the active system like insects. Insects realize the autonomous operation using the excellent structure and the active brain control. Previously, we constructed the 4.0, 4.0, 3.5 mm, width, length and height size micro robot using MEMS technology [5]. The structure and the step pattern of the robot was emulated those of the insect. The MEMS micro robot was generated locomotion by the rotary type actuator and 6 legs. The rotary type actuator used 4 pieces artificial muscle wires. The artificial muscle wire shrunk at high temperature and extended at low temperature. However, rotary type actuator using artificial muscle wires was difficult to actuate for long periods because thermal generation of the artificial muscle wire was larger than the cooling. In addition, the locomotion speed was limited by the speed of shrunk and extend of the artificial muscle wires.

In this paper, millimeter size piezoelectric actuator mechanism for MEMS micro robot is proposed, though the 6 legs and link mechanisms are same as previous MEMS micro robot. The difference is rotary type actuator. The rotational movement was generated by the piezoelectric actuator. The piezoelectric actuator has the potential of long and fast the locomotion.

2 MECHANISM OF MEMS MICRO ROBOT

2.1 Design of MEMS micro robot

The design of fabricated MEMS micro robot is shown in **Fig. 1.** The size of the MEMS micro robot without piezoelectric elements fabricated by the MEMS technology was designed as 3.8, 4.0, 3.4mm, width, length and height. The MEMS micro robot consisted of the rotary type actuator and the link mechanisms.

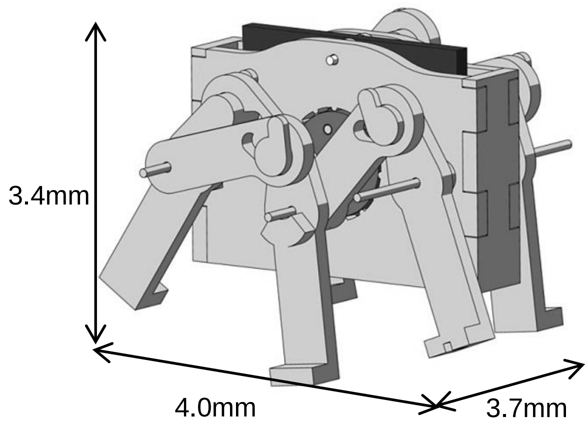

Fig. 1. Design of fabricated MEMS micro robot

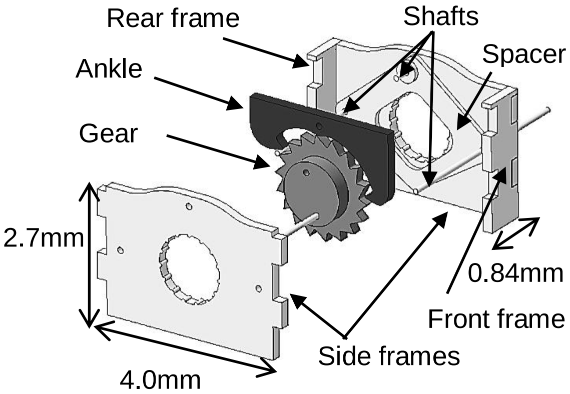

Fig. 2. Design of the rotary type actuator

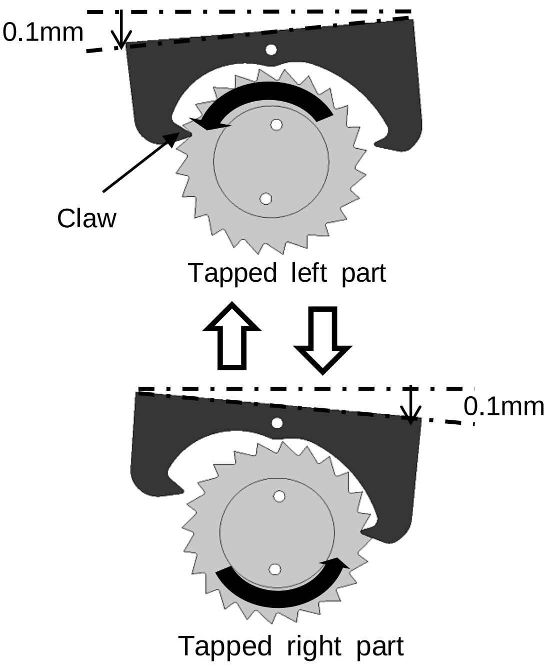

Fig. 3. Rotational mechanism of the ankle and gear

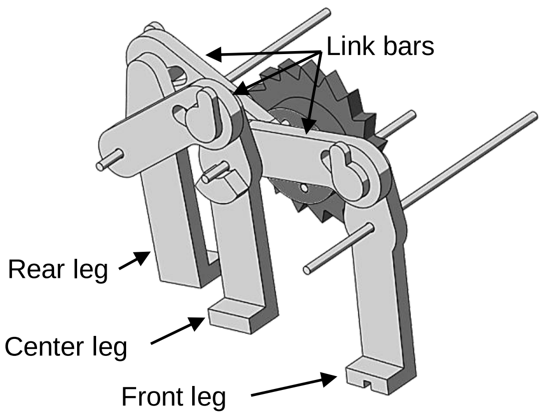

Fig. 4. Design of the link mechanism

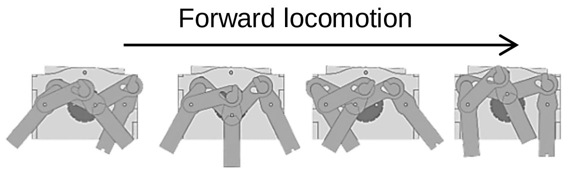

Fig. 5. Schematic diagram of locomotion

The design of the rotary type actuator is shown in **Fig. 2.** The fabrication process of basic components was MEMS technology. The rotary type actuator consisted of frames, an ankle, and a gear. Each frame of micro robot was assembled to join a grooves and tenons. Shafts were fixed in the hole at the top of the side frame. The ankle was connected to the shaft of the side frame. The gear was connected to the hole of the side frame. The displacement of the ankle was designed 0.1mm to generate the rotational movement of the gear.

Fig. 3. shows the mechanism of the ankle and the gear. Alternate tapping the left part and right part of the ankle by piezoelectric elements, and rotational movement of the gear was generated by continuing tapping of the ankle.

Design of the link mechanism is shown in **Fig. 4.** The link mechanism was composed by front legs, center legs, rear legs, and three link bars. The front leg and the rear leg were connected to the center leg by the link bar, respectively. The center leg connected to the gear by the shaft.

Fig. 5. shows the schematic diagram of forward locomotion. The locomotion movement of the micro robot was generated by rotational movement of the gear. The rotational movement was 180 degrees phase shift against the counter side.

2.2 Fabricated Parts

The fabrication process of the micro robot components was based on MEMS technology. The designed shape was formed by the photolithographic process. ICP (Inductively-Coupled plasma) dry etching process realized high aspect ratio machining. The starting materials were silicon wafers with various thicknesses (100, 200, 500μm) which were used depending on the parts.

Fig. 6. shows the fabricated parts of the MEMS micro robot. The gear shaft and the hole in the side frame were designed within the gap of 20μm. The gear shaft and side frame were assembled within the gap 25μm. This gap didn't affect the rotational movement. The link bars and the legs were assembled within the gap 18μm. This gap didn't affect the locomotion.

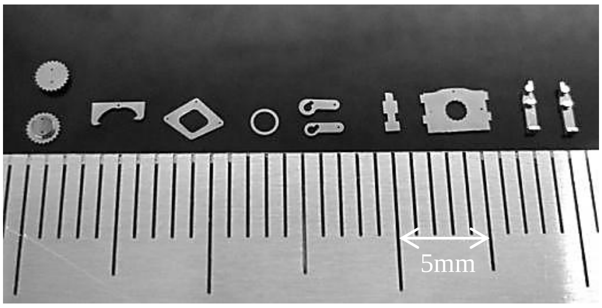

Fig. 6. Fabricated parts of the MEMS micro robot

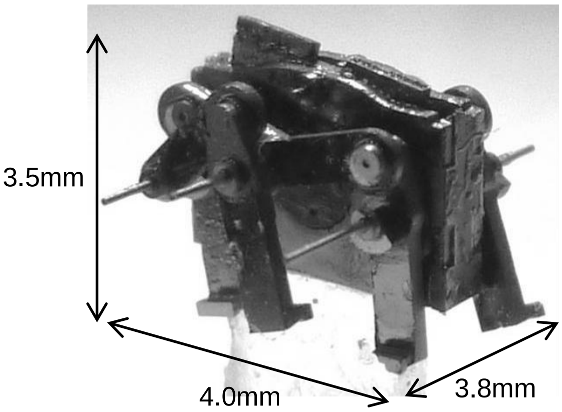

Fig. 7. Fabricated MEMS micro robot

Fig. 7. shows the fabricated MEMS microrobot. The size of the fabricated micro robot was 3.8, 4.0, 3.5mm, width, length and height, respectively.

3 PIEZOELECTRIC ACTUATOR

Schamatic diagram of the piezoelectric actuator is shown in **Fig. 8.** The rotational movement of rotary type actuator was generated by hitting of a pair of hammers using the piezoelectric elements. The piezoelectric elements was 15, 2mm size. The hammer was consisted of piezoelectric elements and a silicon block. The structure of hammer was a cantilever. The rotational movement was 180 degrees phase shift on each side to represent the locomotion of insect. Two hammers were tapping alternate by imputing the anti-phase wave forms. The hammers were connected to the waveform generator and inputted the square wave. The peak to peak voltage was 20V. The frequency of input pulse was based on the resonant frequency of the hammer. The resonant frequency of piezoelectric elements describe as Equation (1). Where f_n is resonance frequency, α_n is resonance frequency constant of cantilever, L is length, E is Young's modulus, I is second moment of area, ρ is density, A.is cross-sectional area.

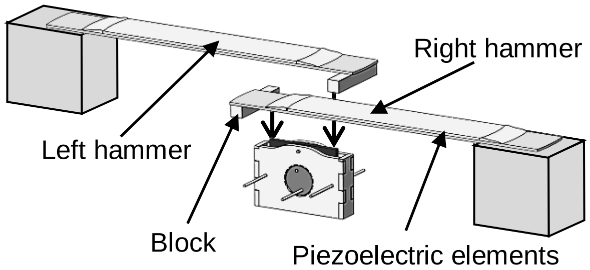

Fig. 8. Schamatic diagram of the piezoelectric actuator

$$f_n = \frac{\alpha_n^2}{2\pi L^2}\sqrt{\frac{EI}{\rho A}} \tag{1}$$

The displacement of piezoelectric elements was maximum when the oscillation mode was ferocity oscillation mode.

The α_n of first oscillation ($\alpha_n = 1.8751$). The calculated resonant frequency of piezoelectric elements was 443Hz. The resonant frequency of hammer was different from piezoelectric element. Therefore, the resonance frequency and displacement of the hammer were measured by laser displacement meter. The input pulse of the hammer was based on the calculated resonant frequency. The maximum displacement of hammer was 395µm. The resonant frequency was 597Hz. A pair of hammers and rotational actuator were assembled and connected to the waveform generator. Therefore, the pulse was inputted to the hammer. The rotational movement was generated by tapping of the hummer. However, the locomotion wasn't generated in the setting parameter. The torque of hammer was not enough to generate the rotational movement of gear. The displacement of the hammer describes as equation (2). Where δ is a displacement of the ankle, P is a weight.

$$\delta = \frac{PL^3}{3EI} \tag{2}$$

The block was used as weights. The mass of the block was regarded as the concentrated load. The displacement of the hammer describe as equation (3). Where m is a mass, g is gravitational.

$$\delta = \frac{mgL^3}{3EI} \tag{3}$$

The displacement of the hammer depends on the number of blocks and lengths of cantilever. The mass of block was 100mg. The mass of the cantilever was increased every 3mg. The block was put on the tip of the hammer. The displacement was measured by laser displacement meter.

Fig. 9. shows the relation of displacement and the mass of hammer. The resonance frequency was changed by varying the mass. Therefore, the resonance frequency of the every measure points was different. This figure shows that the displacement increases in the case of increases the mass.

However, the piezoelectric elements was cracked when the displacement was over 0.9mm. Therefore, the maximum mass was 118mg. The resonant frequency was 235Hz where the displacement was 680μm. As a result, our fabricated robot performed forward locomotion. The locomotion speed was 15mm/min. The proposal piezoelectric actuator mechanism could actuate the rotor for a long period.

4 CONCLUSION

In this paper, we fabricated the 3.8, 4.0, 3.5 mm, width, length, and height size micro robot by MEMS technology. The rotational movement was generated by the rotary type actuator using piezoelectric elements. As a result, the locomotion speed of the robot was 15mm/min. The continuous movement was achieved by using piezoelectric elements without thermal activation.

In the future, we will mount the piezoelectric actuator on the micro robot.

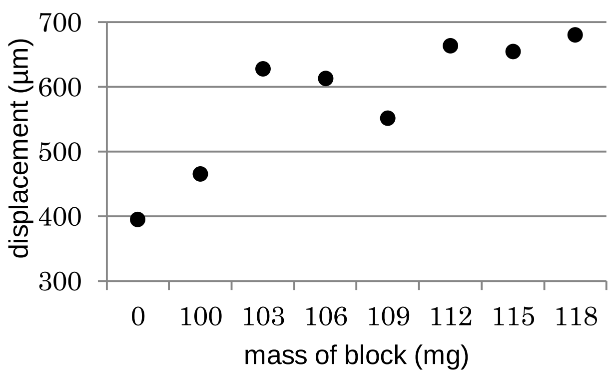

Fig. 9. Relation of displacement and mass of hammer

Abstract: We are developing an autonomous personal robot that will be able to perform practical tasks in a human environment based on information derived from camera images and a laser range sensor(LRS). It is very important that the robot be able to move autonomously in a human environment, and to select a specific target object from among many objects, and these functions will be possible in our system. The robot's environmental recognition system is composed of an autonomous driving system and an object recognition system. First, the autonomous driving system calculates the driving route from the visual information provided by a CCD camera. The robot is driven by this system. The object recognition system proceeds by identifying the specified object using image processing and an LRS, and the robot can grasp the object. An environment recognition system is essential to both of these functions. Here we explain the algorithm by which the robot recognizes the surrounding environment. In addition, we describe the application of this system to our robot, evaluate its performance and discuss our experimental results.

Keywords: Personal robot, monocular camera, Image processing, LRS, Autonomous driving, Object recognition

1. Introduction

In the near future, autonomous driving robots are expected to provide various services in human living environments. To perform these services, the robots will need to grasp the feature of the human environment. Therefore, systems to provide environmental recognition based on image information are being widely studied. However, it is very difficult to recognize all driving environments from image information only; so far, no prospects for such a system have emerged. Therefore, we report on the development of an autonomous personal robot able to perform practical tasks in a human environment based on information derived from camera images and a laser range sensor (LRS), which is used to acquire two-dimensional distance information.

The system for this robot is composed of an autonomous run system for movement and an object recognition system for the recognition and grasping of an object. First, the autonomous run system decides upon a robot driving command based on information in the limited space map. Information such as the placement of walls and barricades is established on to the map, and the data obtained from a CCD camera are compared with the map data. The route is decided, and the robot drives. The object recognition system is composed an object-recognition processing part and a location-information acquisition processing part, both of which use the monocular CCD camera and the LRS. An object is recognized and identified using range information obtained from the LRS in addition to the processed image data provided by the camera. The robot then performs a grasping operation for the object.

2. System view

Our robot has a drive mechanism consisting of two front and two back wheels. The front wheels are attached to a motor that operates the wheels on either side independently, while the back wheels function as castor wheels. This method has the advantage of allowing a small turning radius. To acquire image information, both a single CCD camera with approximately 2,000,000 pixels and an LRS are installed on the head of the robot and can be rotated to all sides by two motors. DC servo motors are used for the robot's drive mechanism, and position and speed control are achieved by the control system of the drive mechanism. The robot also has two arms and hands equipped with sensors, which enable it to respond to the various demands of humans. Finally, an installed wireless LAN can provide remote control for humans. All devices are controlled by a PC, and lead batteries supply the robot's electric power.

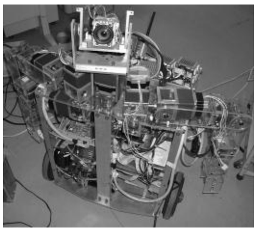

Fig. 1 Our developed robot

3. Specification of the LRS

LRS is a noncontact laser measurement system; our LRS is made by Hokuyo Automatic CO., Ltd. The maximum detection distance of this LRS is 4m. The horizontal plane space is scanned over a 270° angle at intervals of about 0.36° (360°/1024) to detect both the distance and the direction of the target body. This LRS requires a time of only 100 msec for a single scan, and thus a very short distance acquisition time is needed to gain details about the target object recognized with the monocular camera. Fig. 2 shows the externals of the LRS.

Fig. 2 Scanning laser range sensor

4. Autonomous driving system

4.1 System outline

We developed an autonomous driving system for robots that can move in response to image information captured by a monocular CCD camera. It has two subsystems: a route searching system, which decides the course of the robot, and a course correction system, which traces a safe course during the actual run.

4.2 Method for autonomous driving

In this section, we explain the method for autonomous driving. The flow chart for performing autonomous driving is shown in Fig. 3.

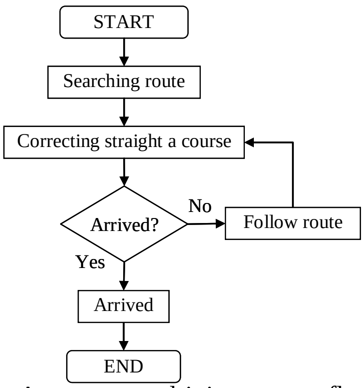

Fig. 3 Autonomous driving system flow chart

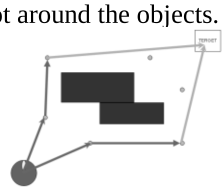
I. Route searching system

In this system, the robot searches for routes based on a limited space map. This map includes information such as the start position of the robot, the goal, walls, and danger zones. When there is a wall and an obstacle on the course to a goal, the robot travels along the middle point between them. The robot always takes the shortest route and removes other routes. Fig. 4 shows two routes that were removed because there are objects in the robot's way, and Fig. 5 shows two routes that are correct because they lead the robot around the objects.



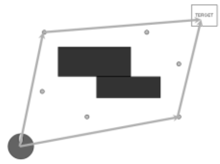


Fig. 4 Removed routes Fig. 5 Correct route

II. Course correction system

Using this system the robot corrects its path by measuring and equalizing the distance on the right and left to prevent it from crashing into a wall.

(i) Data storage

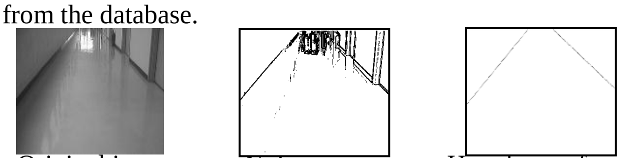
The data consist of the pattern of the slopes of the line on the image, and once calculated, the data are stored in a database. The data are calculated based on the width of the course and the CCD camera angle. The width of the course, direction of the robot, slope of the line and the distance from the center of the course are stored in the database.

(ii) Image processing

The robot acquires the image, and it is processed by edge-based binarization and noise removal. After that, straight lines are extracted, and the image is processed by the Hough transform into straight lines. This process is shown in Fig. 6.

(iii) Self-position correction

The robot estimates its position and direction and corrects the latter by a straight line matched with the data from the database.



Original image Noise remove Hough transform

Fig. 6 Image processing

4.3 Experiment to evaluate the system evaluation

I. Experiment setup

To evaluate this system, we conducted an experiment at Research building 3F of Kyushu Institute of Technology. The total distance that the robot ran was about 35m, and we verified that its systems worked successfully.

The images used in the experiment were acquired from a camera mounted on the robot. This camera was at a height of 875mm from the floor and its depression angle was 20 degrees.

II. Results of the experiment

The robot could reach the goal thanks to the successful operation of the systems. The course correction system was at work during the run. A picture of the course that the robot followed is shown in Fig. 7. As shown, the course correction system worked, so that robot was able to move around obstacles.

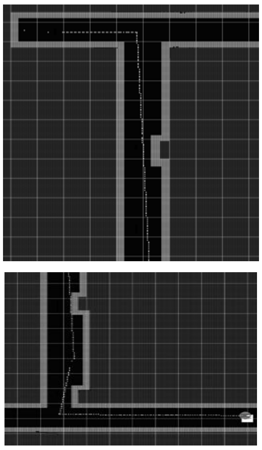


Fig. 7 Results of experiment

5. Object recognition system

5.1 System outline

We developed an object recognition system for robots that can acquire the target object position with image information captured by a monocular CCD camera and range information obtained by an LRS. This system can acquire the object position on the assumption that the object is placed on a desk. The system acquires the location information of the object by using the LRS with the recognized object. Afterwards, the arm is driven based on the location information, and the object can be grasped and held.

5.2 Method for object recognition

In this section, we explain the method for object recognition. The flow chart for the object recognition process is shown in Fig. 8.

I. Object recognition processing

Through object recognition processing, the system can search for objects with image information captured by a monocular CCD camera. The system then searches for the object with the shape and color of the object registered in the database by narrowing the search range to match the camera image step by step. Using this method, objects in the domain can be found. Fig. 9 shows an example of the results of object recognition processing.

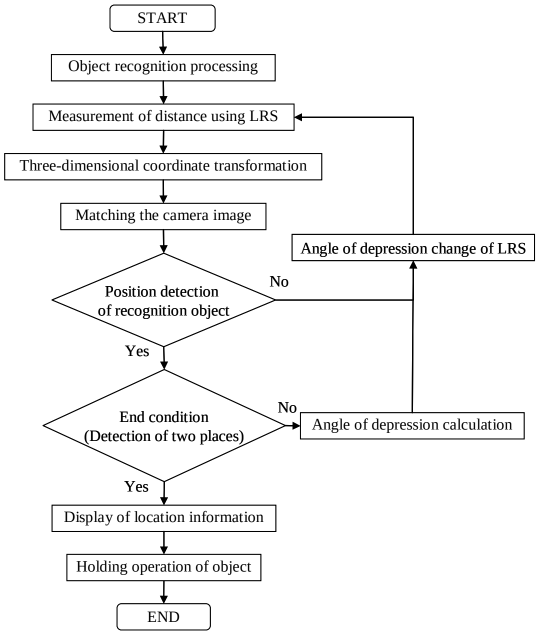

Fig. 8 Object recognition system flow chart

Fig. 9 Object recognition processing

II. Measurement of distance using an LRS

The LRS acquires range information on the object recognized during object recognition processing. The LRS is fixed to the robot head, and moves with the camera. Fig. 10 shows the situation in which the range information is acquired.

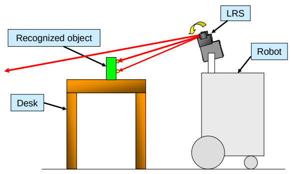

Fig. 10 Position information acquisition

III. Three-dimensional coordinate transformation

The range data of the LRS is range information from the irradiation point to the measurement point of the LRS. Therefore, this range data is converted into three-dimensional coordinates. This conversion is derived in the provided data based on the distance data and the horizontal and perpendicular angles.

IV. Matching the camera image

The system successfully matched the LRS data to the camera image by integrating the camera image with the LRS data.

V. Position detection of the recognized object

The system judges whether the LRS data accurately describes the location information of the object. This involved determining which position of the camera image provides the best measurement point for LRS to detect the object. If the object area recognized in the object recognition processing corresponds to the image coordinates of the LRS measurement point, the measurement can be considered successful. This system acquires three-dimensional coordinates in the vicinity of the center of the object as the location information, provided that the LRS measurement point is at the 60% height level, from the bottom of the object. In addition, to prevent false detection and to provide good, accurate detection, data acquisition is done at a second level on the object (below the 60% mark).

VI. Angle of depression calculation method

The system acquires location information on the object at two places (an upper part and a lower part). After the first set of location information is acquired in the upper part, the angle of depression of the LRS is calculated according to this information. If the distance between the object and the robot can be found, the angle of depression can be calculated from the image information by a geometrical calculation.

VII. Display of location information

When the location information about two places in the recognition object can be acquired, final location information on the object is displayed. Because it is preferable that the acquired positional data reflect the exact position of the object, the area in the center of the two examined places is acquired as the final object location information.

VIII. Recognition of circumference environment

To perform grasping of the recognized object, it is necessary to know the object's circumference. The system acquires the object at center of the camera image, to determine the object's circumference.

VIIII. Grasping operation of object

The target object is located within a certain distance (2 feet) of the robot. Target coordinates are first set in front of the object, based on the acquired object position, and the arm is driven to the coordinates. An image is acquired after the arm arrives, and the remaining drive distance of the arm is calculated from the position of the object and the distance of the hand to the object. The arm is driven again based on the calculated driving amount, and the grasping operation of the object is performed.

5.3 Experiment to evaluate the system

I. Experiment setup

We performed an experiment to evaluate the performance of this system in the grasping operation of an object, in which it searched by object recognition processing. The angle of depression of the camera was set at 10°. Fig. 11 shows the experimental environment when the object was a PET bottle. Its location was on a single-color desk in the laboratory.

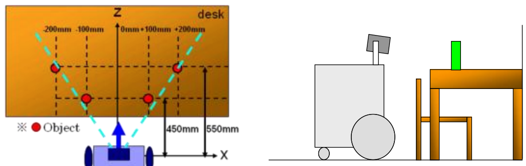

Fig. 11 Experiment environment of the target PET bottle

II. Results of the experiment

As the result of acquiring position information for the PET bottle placed in a variety of places, the maximum error of each set of coordinates was less than 5 mm, and the error in the distance to an object was less than 3%. If the robot is assumed to grasp an object based on this result, we think that it could successfully perform the grasping task.

However, if some parts of the object are hidden, the object recognition may not be able to be carried out correctly. Therefore, it is necessary to improve this system so that it can recognize an object's position based only on some parts of the object.

6. Conclusions

We propose a system that recognizes the driving environment of a robot using image processing and an LRS. This environmental recognition system is composed of an autonomous driving system and an object recognition system. The driving environment of the robot can be processed using these systems, and the behavior pattern of the robot can be expanded within that environment. At present, it is possible for the robot to move in a preselected area, and to locate and grasp a target object. Expansion of the action area and the addition of the transportation operation of the robot with the object are within our sights and will be developed in the future.

Design of robotic behavior that imitates animal consciousness: Construction of the user-recognition system

Motoki Yoshida Kei Ueyama Eiji Hayashi

Department of Mechanical Information Science and Technology
Faculty of Computer Science and Systems Engineering, Kyushu Institute of Technology
680-4, Kawazu, Iizuka-City, Fukuoka Prefecture, Japan

***Abstract*:** Our research has been focused on developing a robot with "consciousness" like people or an animal to enhance the user affinity of service robots. Our laboratory previously conceived a model of the mechanism of consciousness and action and a software architecture based on this model that can be used to control the action of a robot, called the Consciousness-Based Architecture (CBA). Here, we built on this model both theoretically and practically. First, we newly theorized a "motivation model" which assumes that certain motives inhere in the actions of sentient beings, and that the motivational processes involved could become part of the robot's determination of action. Our motivation model is based on the dopamine-generating mechanism of sentient beings. Then, as a practical step toward developing an emotionally interactive robot, we developed a user-recognition system using a CCD camera.

***Keywords*:** CBA, Consciousness of the robot, Motivation of the robot, the user recognition

I. INTRODUCTION

At the present time, not only industrial robots but also so-called "service" robots are being quickly developed. There are various types of service robots: business robots, research robots, welfare robots, and domestic robots, to mention a few. The operation of these robots requires not only the basic functions of robots, such as a high level of intellectual activity, but also the function of user compatibility or affinity so that a user can feel close to the robot as a result of its appearance and behavior. User compatibility implies that the user is easily able to operate the given robot, without getting bored with its use, and can easily develop a sense of closeness with it; ultimately, the user can receive the emotional benefits experienced in relationships with other conscious beings.

Although a robot may gain in user compatibility by being genuinely modeled after a face, it is far more challenging to achieve user compatibility through its behavior and actions, including human-like "capricious behavior". The attempt to give robots "consciousness" such as that identified in humans and animals is a part of these requirements.

Our laboratory has studied animals' adjustments to their environments in an attempt to emulate animal behavior. We constructed a hierarchic structural model in which consciousness and behavior were hierarchically related. Based on this model, we developed a software architecture we call Consciousness-based Architecture (CBA). CBA introduces an evaluation function for behavior selection. Here, we elaborate on the evaluation function, using the dopamine-based motivational system as its basis.

For the present study, we developed a robotic arm that has six degrees of freedom, so that the arm could autonomously adjust to a target position. Fig. 1 shows an overview of the robotic arm. The robotic arm that we used has a hand consisting of three fingers in which a small monocular WEB camera is installed. The landmark object is detected in the image acquired by the WEB camera. Previously, as an autonomy action experiment, CBA was applied to the robot arm and the behavior was then inspected.

This paper describes a user-recognition system that can judge a specific person using a CCD camera, and integrates the user-recognition system and CBA. We tested the system to identify target users from among five persons.

Fig. 1 Overview of Robotics arm

Fig. 2 CCD camera

II. SYSTEM STRUCTURE

Fig. 3 shows the appearance of the robot arm, and Fig. 4 shows its degrees of freedom. The robot arm has 7 levels of flexibility {shoulder (Joint1, Joint2), elbow (Joint3, Joint4), wrist (Joint5, Joint6), and finger (Joint7)} at its full length of 450 [mm]. The hand part has 3 fingers with one flexibility; the weight of the main part is about 0.8 kg. A small Web camera, installed at the tip of a robot arm, can recognize the external situation. The web camera and the robot arm's actuator are controlled by USB communication.

Fig. 3 robot arm

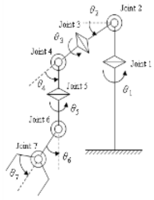

Fig. 4 degree of robot arm

III. AUTONOMOUS BEHAVIOR

1. The motivation of the robot

Most robots are pleasing to people because of their unique movements. However, the action *choices* of robots are too objective in orientation. Action choices that resemble those of subjective human beings and animals are needed to enhance user compatibility. Therefore, we at first considered the structure of sentient action. When an animal, including a human being, takes some action, it can be represented by a flow chart such as "Recognition → Comprehension → Motivation → Action", shown in Fig. 5. On the other hand, the action of the robot tends to eliminates motivation in the simple flow "Recognition (Comprehension) → Action"

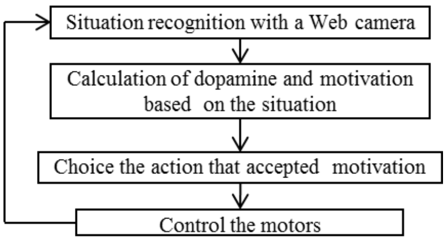

Fig. 5 Flowchart of this system

2. Situation recognition with a Web camera

The first step of the "humanized" robot's system would be to recognize a situation. For this purpose we devised a labeling image (Fig. 6), taken by the Web camera installed on the robot hand. We programmed the system to divide the image into green, blue, and flesh-colored blobs and extract the shape, size, and center of gravity position. From this information and the posture of the robot arm, the robot could recognize the position and its distance from the target-color object. Furthermore, the system memorized the central point for three frames.

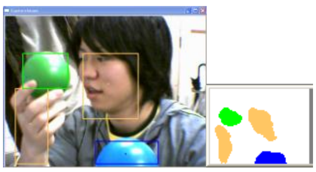

Fig. 6 Web camera image and a labeling image

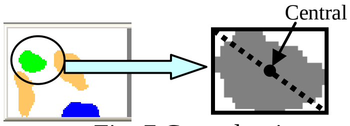

Fig. 7 Central point

3. Calculation of dopamine and motivation based on the situation

When a man and an animal interact, changes occur in the dopamine level in the brain. The dopamine-generating locus was regarded as model for determining the robot's motivation, and was copied for the control model. The control model is shown below. In the graph, sample changes in , ω_n and ζ are shown. T

Rising $y''+2\omega_n\zeta y'+\omega_n^2 y-\omega_n^2 u_{(t)}=0$

Decaying $y=e^{-t/T}$

ω_n : natural angular frequency : earliness of a rising

ζ : braking rate : height of the peak of a rising

T : time constant : attenuation performance

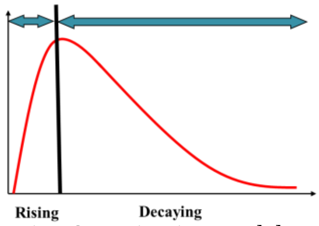

Fig. 8 Motivation model

In the control model dopamine is generated with reference to pleasant or disagreeable stimuli with variables ω_n, and T are determined by the outside environment and the internal state, respectively. Moreover, it is defined by asking for total of the generated dopamine and calculating the secondary delay response in such a way that the total is considered as the input into a robot's motivation.

4. Choice of the action that accepted motivation

The action level was set up by dividing a robot's motivation by a fixed value. In this way, the actions that could be chosen for each action level were limited.

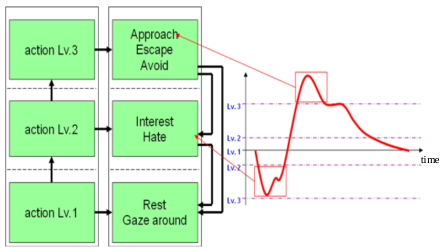

Fig. 9 Choice of the action based on motivation

5. Consciousness architecture (CBA)

Fig. 10 shows a diagram of the hierarchical structure model called CBA (Consciousness-based Architecture) which relates consciousness to behavior hierarchically. The characteristic of this model is that the consciousness field and behavior field are built separately. In a dynamic environment, this model determines the consciousness level appropriate to the environment, and the robot then selects the behavior corresponding to that consciousness level and performs the behavior. This model is characterized in that the consciousness level approaches an upper level so that the robot can select an advanced behavior when certain behavior corresponding to the consciousness level is discouraged by some external environmental factor.

Additionally, an upper-level consciousness can make a choice of a low-level behavior. The mechanism of this model is that it selects the optimum behavior within the low-level behaviors, to achieve the robot's goals.

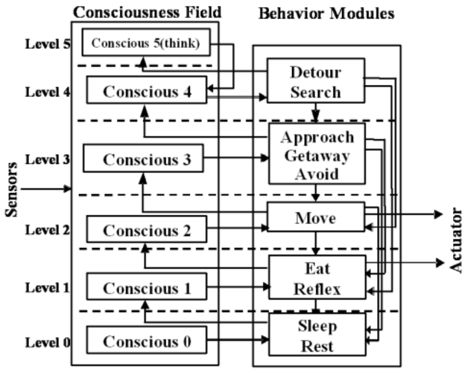

Fig. 10 Consciousness-based Architecture (CBA)

IV. USER-RECOGNITION SYSTEM

4.1. Outline of the system

From an image provided by the CCD camera, the system detects a moving object and carries out a search in its data domain. It pays attention to the shape and color of the object and determines whether it is either a non-human object or a human being. In addition, it detects the parts of person's face and compares each person it encounters with user information on a database. The flow for user recognition is shown in Fig. 11.

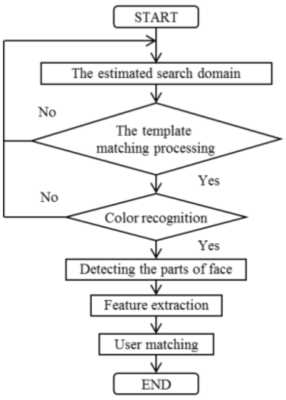

Fig. 12 Difference Image

Fig. 11 System flow Fig. 13 the maximum height

4.2. The estimated search domain

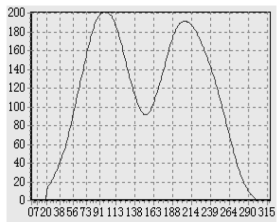
This process estimates the domain of a human being is from the information provided by the differences between the frames.

4.2.1. The detection of height

This system detects the maximum height Y of each X point in the image from the differential image which it acquired from the differences between the frames. The image from these detections is shown in Fig. 12.

4.2.2. Average

This system makes a smooth graph by creating an average by 40 pixels of values of the height Y which it detected at the maximum, because the position sensing of the domain is difficult only at the maximum height Y. An image of average values is shown in Fig. 14.



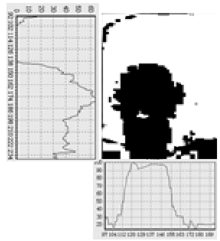


Fig. 14 Graph of the average Fig. 15 Histogram

4.2.3. The detection of the search domain

From the graph, the system detects the part at the top and estimates the position of the human being. Next, it scans from a person's position detects the point below the top or the point that is lower than 1/3 from the height of the person's position. One can assume that a part surrounded by points is a search domain.

4.3. The template-matching processing

When this system begins its operation, it reads the template that imitates the head of a person. The outline acquired in the previous process is compared with the template. The size of the template changes according to the size of the search range. Generally, this process requires a great deal of calculation time. Real-time operation is achieved by reducing the number of comparisons. When the matching rate is higher than the threshold and reaches its maximum, the position is output as the position of a human face.

4.4. Color recognition

An image is difficult to identify using only conventional processing. The system has to finally confirm that the image is that of a human being. Skin color is used to ultimately determine this, using the template-matching process to decide the identity and position of the human image. In this case, color information processing uses the HSV color model.

4.3. Detecting the parts of face

The robot automatically makes a histogram of external color pixels for the X and Y coordinates and judges the position of the face from the histogram. The image of the histogram is shown in Fig. 15.

Then, it detects the eyes and nose of a face through a Gabor filter in a 90 degrees direction.

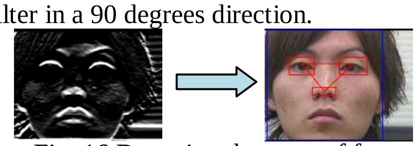

Fig. 16 Detecting the parts of face

Gabor Filter

$$g(x,y,\lambda,\theta,\psi,\sigma,\gamma)=\exp\left(-\frac{x'^2+\gamma^2 y'^2}{2\sigma^2}\right)\cos\left(2\pi\frac{x'}{\lambda}+\psi\right)$$

$$x' = x\cos\theta + y\sin\theta \qquad y' = -x\sin\theta + y\cos\theta$$

λ: The cosine component of wavelength

θ: The direction of the striped pattern on the Gabor function

ψ: A phase offset γ: A aspect ratio

4.4 Feature extraction

As shown in Fig. 17, the distance from a nose to eye is A and the distance between the eyes is B. The robot computes B/A.

It combines and equalizes each image through a Gabor filter pass every 30 degrees. The new image is shown in Fig. 18.

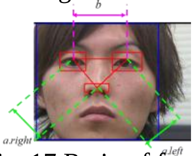

Fig. 17 Ratio of face

Fig. 18 Gabor filter picture

4.5. User matching

It compares the extracted features with the information of the people stored in the database, and checks whether the user is a known person.

V. Experiment

5.1. Experimental method

The system's performance was evaluated with two experiments.

Template matching rate:

1. In whether a user is a particular target person using five different target persons.
2. Matching User A' s template with Users B~E.

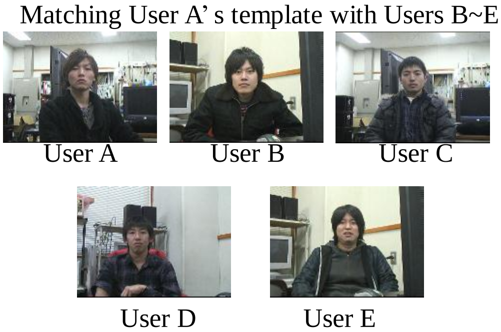

Fig. 19 Objects

5.1. Experiment 1

The result of experiment 1 are shown in Table 1. This system had about a 70 percent recognition rate of the target person. However, since the user's expression always is not the same, the template matching rate can fall.

Tab.1 Result of experiment 1

	User1	User2	User3	User4	User5
1times(%)	77	69	73	70	73
2times(%)	71	73	73	70	76
3times(%)	63	72	68	72	70
4times(%)	72	72	71	71	70
5times(%)	70	71	69	71	50
Average(%)	70.6	71.4	70.8	70.8	67.8

5.2. Experiment 2

The results of experiment 2 are shown in Table 2. When the user differed from the target person, the matching rate dropped below 50 percent.

Tab.2 Result of experiment 2

	User2	User3	User4	User5
1 times(%)	48	47	53	48
2 times(%)	45	41	44	44
3 times(%)	52	41	49	46
4 times(%)	45	43	50	44
5 times(%)	57	46	48	55
Average(%)	47.4	43.6	48.8	46.8

VI. CONCLUSION

In this paper, we created a user-recognition system using a CCD camera. It became possible to identify the target person among 5 different people.

In the future, we will further develop the theoretical and practical tasks needed to design a robot with user affinity, and one that recognizes the user's expression.

Abstract: We propose a novel approach to support teacher's work in an unpredictable learning environment, such as a robotics class. The Conflative Learning Environment (CLE) approach blends the roles of the student, the teacher, and the software developer by taking the diverse users of the learning environments beyond their traditional, fixed roles and blending the users' activities and working environments with each other. We report results from a qualitative study indicating that a novel monitoring environment developed by following the CLE approach helped teachers to recognize students' particular problems better than when observing the students without such support. Results of the study have been used to guide us in the further development of the CLE approach and the monitoring environment.

Keywords: agent, intervention, learning environment, robotics

1 INTRODUCTION

Educational robotics has a recognized status as an attractive tool for modern learning environments. Cheap and highly accessible robotics sets, such as Lego Mindstorms, provide a platform for different kinds of learning scenarios ranging from basic technology education in a primary school to advanced artificial intelligence studies in universities. Learning settings in robotic classes emphasize students' active participation and group-oriented working methods. These kinds of learning settings, especially at an elementary level, however, pose a particular challenge for teachers: How to follow all students' or an individual's activities? Project-based working methods, open-ended tasks, various problem solving strategies, and the iterative nature of robotics projects easily lead the students to take different paths in their work. This makes it difficult for the teacher to detect the students' problems and the right moments for intervention.

Traditionally, intelligent tutoring systems (ITSs) have been used to guide students and teachers in such learning settings. The deductive student modeling approach traditionally used in ITSs is based on pre-defined rules to model and predict students' progress in the learning environment. The systems reveal only the result of a modeling process to the teacher. However, the unpredictable nature of a robotics class requires that the learning environment leaves room for the teacher to explore through *abductive reasoning* what factors actually have led the students to the current situation.

In this paper, we present a *conflative learning environment* (CLE) approach that enables blending of roles. The teacher can adopt a software developer's tasks in his or her own work. This allows the teacher to exploit abductive reasoning to explain observed phenomena in the teaching setting, and to intervene accordingly.

This paper is organized as follows. In the next section, we review previous approaches to tackling the problem of tracking student activities in learning environments where unpredictable events easily take place. We describe how the CLE approach differs from the existing solutions. Then, we present the main findings from a qualitative study that analyzed the use of a monitoring environment built by following the CLE approach.

2 BACKGROUND

In previous research by other authors, the student modeling approaches are mostly theory-driven. The environments, based at least loosely on ITSs, have offered a selection of pre-defined choices by which the monitored data is classified and used for modelling the students. These systems give support for observing the overall progress of all students in the classroom, detecting the problems that the students have, and analyzing the actions of a particular group or even an individual student. Despres and George's research [3] is probably one of the closest to our approach in the educational robotics domain. They describe an intelligent tutoring system that allows the teacher to follow the students' activities in an educational robotics classroom. In the first instance, their system provides support directly to the students, and if that fails, the system reports the difficulties to the teacher as well.

The main difference between the existing and CLE approaches is that, whereas many traditional ITS applications use a theory-based approach for building the learning model, the learning environments based on the CLE approach start from the empirical observations arising from the current learning situation. There are ITSs that apply an empirical approach for building the learner model (for example a multimedia ITS for Geometry by Cooper et. al [2]). However, the learning models in these systems are still at least partially predicted by theoretical assumptions. For example, a given set of features classifies the user's emotional self concept [2].

3 CONFLATIVE LEARNING ENVIRONMENT

A conflative learning environment (CLE) is a novel kind of open and flexible learning environment that was developed based on the observations that the Finnish authors of this paper have gathered during 10 years of running Kids' Club. Kids' Club is a combined after-school robotics and technology club and a living laboratory for designing novel educational technologies in conjunction with their intended users, particularly students and teachers. During the development of the club concept in various school and after-school settings, we have shown that the group-oriented working methods, iterative problem solving processes, group dynamics, and students' different roles in the groups easily lead the groups and individual students to proceed quite differently with their projects. Hence, there is a need for a framework to support the development of learning environments that allow the teacher to explore the learning process deeply.

2.1 Role blending in the CLE approach

The traditional division of the roles in educational technology development processes usually strictly separates the roles of developer, teacher, and learner from each other. Moreover, the tasks undertaken by these process participants usually follow each other in a cycle with predefined steps. The *Empirical Modelling* (EM) approach breaks this division by taking the users of the learning environments beyond their traditional roles and by blending their activities and working environments with each other [1]. In particular, EM has tools that allow the teacher to model students' behavior by his or her observations, thus - to a certain extent - becoming a developer.

The role blending in the CLE approach can take place between the teacher and the developer, the student and the developer, or even between the student and the teacher. The role blending takes place through cyclic processes where the users contribute to building the learning environment gradually by modelling the empirical observations arising from the current learning setting (Figure 1). Modelling is an essential process for a functional learning environment. Traditional learning environments require advanced programming for enhancing the learning environment to match the unexpected, and hence unprogrammed, student behavior. In contrast, EM supports modeling that can be done without interrupting the learning process.

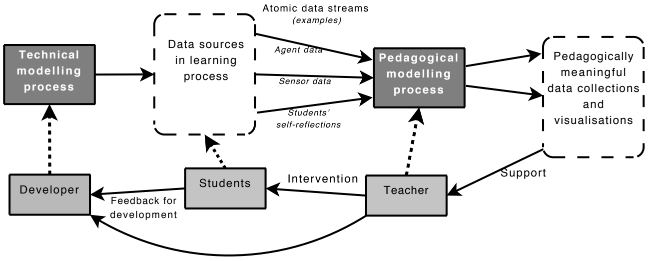

Fig. 1. Example structure of an application based on the CLE approach

2.2 Working processes in the CLE approach

The modelling process in the CLE approach (Figure 1) is based on individual data streams originating from the current learning process. The data can be, for example, information about the users' activities within the learning environment, or automatically collected sensor data, or students' self-reflections about their progress. A learning environment based on the CLE approach should provide appropriate tools for the teachers to process this primary data to obtain pedagogically meaningful collections that can be visualized. As an abstract approach, the CLE does not limit or define the ways in which the user can combine the primary data, or how the observations are presented. A CLE distinguishes development from modelling activities. When building a learning environment by following the CLE approach, there is, indeed, a need to have "traditional" software developers involved. They prepare the tools and the environment so that the users can then make their contribution whilst modelling *as if* in the role of a developer. 'Modelling' means that the users reflect upon their own surrounding and working environment through their observations of the learning environment.

Jormanainen et al proposed in [4] that to make the applications based on the CLE approach more accessible for the users, modelling of the learning process should be divided into two parts. The first part, *technical modeling,* consists of setting up the basic modules of the environment. This part of the modelling process can take place before and even between classes, when the model can be redefined to meet the new requirements. The second part, *pedagogical modelling*, is the process that takes place during the classes. In this part of the modelling process the teacher defines the environment by identifying data collections meaningful for the teaching context and visualizations for the data that the agents collect. It may be that the collections and visualizations of a given instance are not usable elsewhere; for instance, they might depend on the phase at which the students are in their project. To put our work in context, we classify learning environments between the theoretical extremes of *model-based* environments and *modelling-based* environments (Table 1). The model-based environments are traditional ITSs that take deduction as a starting point for the learner's modeling. At the other end, inductive modeling-based environments take empirical observations arising from the current learning setting as a starting point for modeling. It is important to recognize that these are theoretical extremes, and real systems usually fall between these alternatives, for instance, when an abductive approach to modelling is adopted.

Table 1. Model-based and modeling-based learning environments (based on [4])

	Model-based	**Modelling-based**
Modelling approach	Theory-based, deductive	Empirical, inductive
Learning model	Given	Constructed
Adaptation	Black box	Transparent
Roles in the learning community	Separated	Blended
Working environments	Separated	Conflated
Direction of modelling	Top-down	Bottom-up
Modifications to the tools	Through the software development process	On demand in the actual learning situation

4 OPEN MONITORING ENVIRONMENT

To help the teachers working in a robotics class, we have developed an *Open Monitoring Environment* (OME) by following a cyclic process of defining, testing, and evaluating as proposed in the CLE approach [4]. The core idea of the OME is to help the teacher to detect the right moments for intervention in a robotics class and help to build his or her intervention strategies. The students design and build robots with Lego Mindstorms educational robotics sets, and they program the robots by using a visual programming environment. The OME automates data collection from the learning process by utilizing agents to observe students' interactions within the robotics environment [4]. In addition, the OME environment contains a specific modelling environment for the teacher, where he or she can build the model representing the current learning scenario.

5 ANALYZING CLE AND OME

A qualitative analysis of the OME was conducted in a real school setting, where teachers used it for monitoring students' activities in the robotics class. The main focus of the experiment was to address the question: *How does the OME help the teachers who are working in a robotics classroom?* Four teachers and 12 primary school students participated in the study. The participants were divided into two groups of two teachers and six students. During the study, the students worked in pairs for a given robotics task for a period of three hours. Neither teachers nor students had prior familiarity with robotics. The student groups were provided with pre-constructed wheeled robots, and a simple programming task was given to them. The teachers' work during the experiment can be roughly divided into two parts. First, they observed students' actions through the OME environment. When the agents delivered new data to the modelling environment, it was automatically updated to reflect the current situation. Secondly, the teachers used this output to determine when it was appropriate to intervene in students' work (e.g. when they observed a problem). Data collection in the study was conducted in several ways. First, teaching sessions were recorded with a video camera. Second, data produced by the agents based on the students' actions was saved to a database. Third, teachers' actions with the OME were saved to log files. Finally, video-recorded interviews with the teachers were conducted. The research material was analyzed qualitatively. After transcribing the video and interview material, a codebook was built to help the analysis and make the analysis consistent. Before the actual analysis, the reliability of the codebook was tested statistically. Transcribed video and interview material was analyzed by categorizing material according to the codebook with the ATLAS.ti software.

The focus of the qualitative analysis was to identify the opportunities that the OME brings to teachers' work, and to identify the role that EM principles and tools play in implementing an environment based on the CLE approach. The new ideas and teachers' opinions about the additional information that the environment should provide were appreciated as potentially very valuable for improving the OME further. This process is an essential part of the CLE approach. The outcome of the research process serves as an input for the next iteration of technical modelling, and it also helps the researcher to identify ways in which the teacher adopt the role of developer in accordance with the CLE principles.

6 RESULTS

The qualitative analysis of the experiment material shows that the OME helped the teachers to intervene when the students had problems in their robotics exercises. The teachers were able to make informed decisions on what particular issues they would follow from the students' learning process based on the agent data. Furthermore, the teachers were able to recognize students' particular problems through the OME system better than when observing the students without such support. This was especially evident in situations where only one of the teachers was following the students' progress through the OME. In these cases, the teacher in the classroom did not notice that the students were having problems, but another teacher was able to see this through the OME and help the group with the problems. Most of these cases were related to technical problems when the students were unable to upload code to the robot due to the unreliability of the infrared link between the computer and the robot. It was typical for these cases that the students did not ask for help but repeatedly tried to upload the code to the robot, despite the error messages.

7 DISCUSSION

This experiment focused mostly on how the teachers used the OME. It is evident that the OME was beneficial for the teachers especially because they were novices in working with a robotics environment. However, as the idea of the CLE approach is to blend the roles of the teacher and the developer, the issue of being involved in the development was also introduced to the teachers. It was surprising that the teachers actually agreed that they could also develop the environment further if this was a natural part of the work flow. When the teachers looked back on the actual learning process and reflected on how different decisions might have enhanced the quality of the learning process, they identified both key pedagogical issues and ways in which these might be addressed by modifying the learning environment. These issues could then have an impact on the design of a learning environment based on the CLE approach. This means that, by reappraising their decisions, teachers working with the CLE approach blended their traditional role with the role of a system designer.

8 CONCLUSION AND FUTURE WORK

The study reported in this paper gave us more evidence that Empirical Modelling has potential to support role conflation even more deeply than the current implementation of the OME allows. To realize this more effectively in practice, further development is needed to ensure a seamless integration of the EM tools with the learning environment construction process defined by the CLE approach. The analysis of the qualitative data and teacher's work in the classroom guided us in developing a data mining module for the OME [5] to enable automatic processing of agent data. In contrast to traditional data mining applications, a teacher can reconstruct a training set for a data mining algorithm on an on-the-fly basis and apply a new classifier in the environment at any time. The rules associated with the classifier are exposed for the teacher's revision. If the teacher is not satisfied with the resulting classifier, he or she can always modify the rules and changes will be effective immediately. Results from the study indicate that this open data mining process produces pedagogically useful and interpretable information about the students' progress with relatively small datasets [5].

Department of Electronics and Communication, BMS Institute of Technology, Bangalore.

Abstract

In this paper we describe a model approach to realize a three dimensional copy of an object with the help of claytronics. Claytronics is a form of programmable matter that takes the concept of modular robots to a new extreme. Programmable matter refers to a technology that will allow one to control and manipulate three-dimensional physical artifacts (similar to how we already control and manipulate two-dimensional images with computer graphics). In other words, programmable matter will allow us to take a big step beyond virtual reality, to synthetic reality, an environment in which all the objects in a user's environment (including the ones inserted by the computer) are physically realized.

Here we discuss a way to realize a 3D facsimile starting with image/shape acquisition continuing with transmission and finally the process completing with the 3D realization of the target object. We describe the process of image/shape acquisition with two separate methods where the selection of the method is purely dependent on the object. Transmission can be achieved by conventional means. For the object realization we describe an algorithm which can fulfill the purpose.

I. INTRODUCTION

Most of the literature here that is in this section has been sourced directly from earlier papers on claytronics [1], [2]. The idea is to first acquaint the reader with the concept on claytronics.

The whole purpose of claytronics and our work in particular is to create an ensemble of tens or even hundreds of small autonomous robots which could, through coordination, achieve a global effect not possible by any single unit. One of the primary goals of claytronics is to form the basis or a new media type pario. Pario, a logical extension of audio and video, is a media type used to reproduce moving 3D objects in the real world. A direct result is that claytronics must scale to millions of micron-scale units. Having scaling (both in number and size) as a primary design goal impacts the work significantly. This allows us to render physical artifacts with such high fidelity that our senses will easily accept the reproduction for the original. When this goal is achieved we will be able to create an environment, which we call synthetic reality, in which a user can interact with computer generated artifacts as if they were the real thing. Synthetic reality has significant advantages over virtual reality or augmented reality. For example, there is no need for the user to use any form of sensory augmentation, e.g., head mounted displays or haptic feedback devices will be able to see, touch, pick-up, or even use the rendered artifacts.

A futuristic scenario involving claytronics could go like this. An explorer or a naturalist may come across something interesting in his expedition. If the person wishes to communicate this find with fellow scientists he or she can do it by a normal two dimensional image. However if he wants to go beyond that (i.e. communicate not just with X and Y co-ordinates of that object) but involve the 'depth' and 'feel' of the object then Claytronics would be the solution. Using sophisticated image acquisition techniques, the object can be documented. This can be subjected to various processes and then transmitted. At the receiving end using an ensemble of robotic modules a facsimile of the object can be achieved thus the whole process happening in real time.

II. THE PROCESS IN A NUTSHELL

In this section we briefly go over the entire process we plan to achieve. The complete plan and the details do not form a part of the following literature. They are discussed in greater detail in the design section.

To achieve a complete 3D fax machine there are three parts to the system [3]. Shape acquisition, remote transmission, shape reconstruction. This forms the complete loop. Image acquisition can be of two types. For objects whose 3D fax to be obtained has a very small size (the term small here is greatly dependent on the number of claytronic atoms we are in possession of) we have a way of acquiring the image [3] and for objects very much greater than the mass of the ensemble we propose an entirely different way of acquiring the image. While many papers have discussed the former the latter has rarely been given its due. Our belief is that for claytronics to be fully made use of both are very important because many objects we encounter has its size always greater than the mass of the ensemble. While small objects can be sampled by applying the catoms tightly over the surface the big objects can be handled by sophisticated image processing software. In this paper, we briefly describe a method to acquire a 2 dimensional image. Using several 2D images a rough 3D feel can be given to describe. Here again the correctness of the 3D image that is constructed depends on the object and the number of 2D images from which it is constructed. This 3d 'feel' is stripped to its most basic form, points of interest are marked. Further processing is done and this can be transmitted using sophisticated techniques.

After acquisition and transmission comes the shape reconstruction. For reconstruction we start off with a simple co-ordinate feeding message. For convenience purposes we are developing the algorithm for 2-dimensional shapes only. The algorithm can b extended to 3-dimensional objects too, without much difficulty. For implementing the algorithm to the 2-dimensional shapes a very important generalization has to be made. This generalization is like a 'torch bearer'. It holds good for any kind of 2-dimensional shape. The generalization is that all 2-d objects can be described in the form of co-ordinates. This generalization is fairly obvious. In claytronics however the co-ordinates defining is not restricted to the outline or skeleton of the object alone. The co-ordinates here should describe each and every point in the object. A parallel analogy can be made with Digital image processing. These positions/co-ordinates are obtained at the end of the shape acquisition process. And the object can be better described/realized depending on module size. Lesser the module size greater the number of co-ordinates to better assess the object and realize it and greater the module size lesser the number of basic constituents. Therefore the error here is dependent on the size of the module. Alternatively we can even say that error is dependent on the number of co-ordinates. First let us let us go about the task of achieving 3 dimensional rendering of typical ordinary shapes. Once this is achieved moving on to complex shapes is not difficult. As an illustration we take a real life example and illustrate how to achieve it in 2-dimensional XY frame. The same can be extended to the three dimensional frame. At the receiving end the shape formation algorithm is applied and the fax is obtained. For parallel comparison and correction, the 3d image can be reconstructed. This reconstruction however is done by the computer. A big advantage gained here is the degree to which the fax deviates from the original object is always known and repeated iterations can be done to achieve a greater precision.

Additionally, we draw a parallel between image processing and claytronics, and show that both are 'cut from the same cloth'. We will also show you that, certain cases demand a particular kind of approach and in certain other cases we borrow techniques from actual module motion [4].

III. DESIGN

In this section we give a complete detail of the entire process. The advantages and disadvantages are thoroughly debated and possible extensions to the whole idea are added later on. Let us go about each of these processes starting with shape acquisition. As said earlier basically there are two ways in which shape can be acquired. The applications of claytronics using the camera approach are very vast and profound. Particularly multicamera stereo systems can capture dense shape information which can be transmitted in real time using suitable algorithms [6]. Structured light approaches based on scanning lasers can also be used [7], [8]. Alternatively for faxing small objects we can go for contact sensing where the programmable matter reads the shape of an object by direct contact with its surface.

However, here we also focus on the method of capturing of the image by camera for shape acquisition. For the sake of simplicity and understanding we will show it only in two dimensions

1) *Shape acquisition*

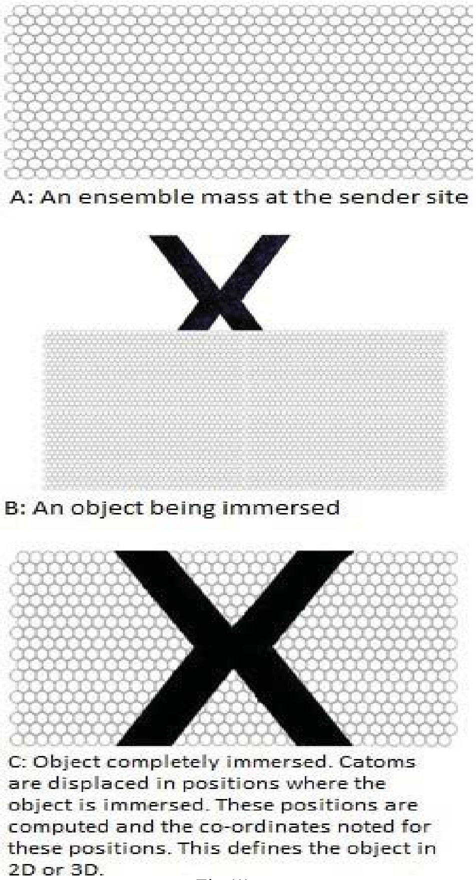

Fig (1)

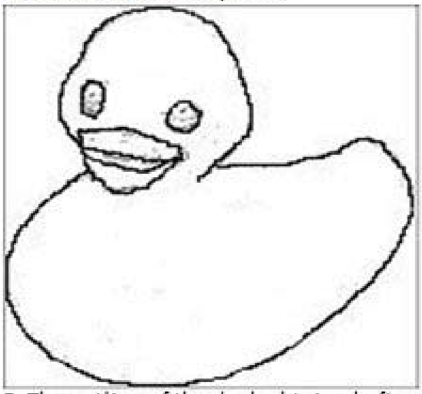
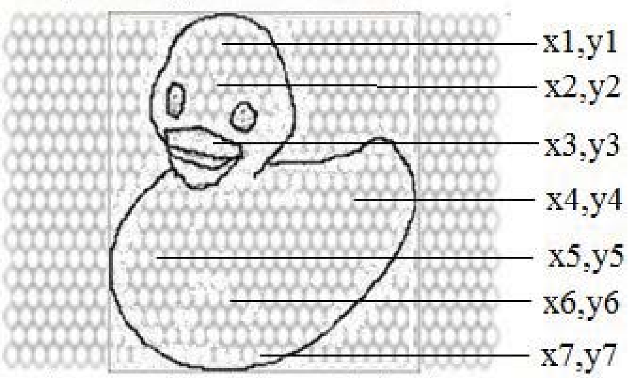
The process of image acquisition can be done by two techniques. The first is the contact sensing wherein the object is immersed in the ensemble and the catoms can read the shape of the object by direct contact with its surface. This process can be used only for those objects which are small enough to be immersed in the ensemble. Common sense obviously dictates this process cannot be used for buildings, cars, etc. The process starts by immersing the object in the ensemble. When the object is completely immersed and the catoms tightly applied to the object, the ensemble is scanned to recognize which catoms are missing from their regular positions. For effective implementation, the positions of the catoms in default position or when no object is immersed has to be known. This is compared with the catoms whose positions have been displaced i.e. after object immersion. This gives us the co-ordinates that describe the object in space. For proper reconstruction at the receiver side, the coordinates of those positions where the catoms are absent make more sense. Hence the computer now computes the coordinates of the positions where the catoms were displaced. These critical co-ordinates are then transmitted. This process is illustrated in fig.1

A: Picture of a dummy duck



B: The outline of the duck obtained after processing. This method can be used to take 2D images of 3D objects, combine them and after further processing we can get a rough 3D sketch or grid. A simple 2D image is shown for clarity.



C: The outline of the duck is overlaid on the ensemble. For a 3D realization the surface contour is overlaid on a 3D dimensional ensemble. The computer determines the co-ordinates which form a part of the ensemble. These co-ordinates are then stored or transmitted.

Fig (2)

The second and perhaps a more robust technique which can be used for all types of objects is the non-contact sensing. If the object under consideration is a 2-D object, then a single photograph of the object would suffice. As mentioned it is assumed that the computer knows the coordinates of all the catoms. First the photograph of the object is input to the computer. Describing the process in crude terms, the computer takes the outline of the image and overlays this outline on the virtual ensemble. By simple image comparison the catoms that come inside the overlay or form a part of the overlay can be seen. The co-ordinates of these catoms are then taken and stored. When shape reconstruction is required at the receiving end these co-ordinates are transmitted. The process is illustrated in fig.2.

2) Shape reconstruction

Shape reconstruction is the most important step in claytronics. This can be primarily divided into two stages: the activation stage and the grouping stage. We propose methods to achieve each of these.

Activation

At the end of acquisition the computed set of lattice positions is transmitted and at the receiver site we have these positions. These positions can be the Cartesian Co-ordinates for the required shape to be formed. Depending on the object that we wish realize the number of transmitted co-ordinates may vary. These co-ordinates are stored at the site, till we wish to achieve the realization. Initially the ensemble is powered on, but the catoms are still in the dormant state. The first step is to activate the catoms belonging to the shape to be realized. One way of doing this is illustrated in the figure.

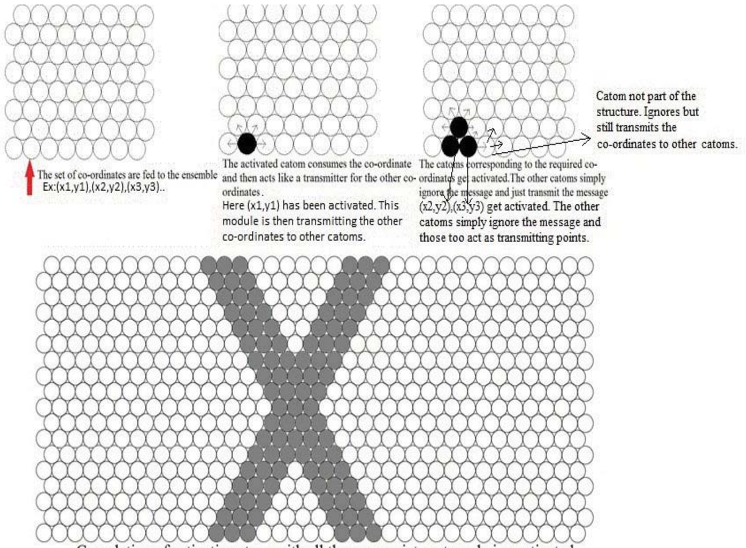
Initially the coordinates are to be fed into the ensemble. Loading several coordinates at a time might result in chaos. So we go for a technique used popularly in networking. We modify it here suitable for our application in claytronics. In claytronics we make the assumption that each module knows its position and location with respect to entire ensemble. Borrowing a technique used in a noiseless channel (stop-and – wait protocol [9]), the receiver sends/feeds one position co-ordinate to the ensemble and stops till it receives a confirmation from the ensemble and then sends the next co-ordinate. We have unilateral communication for the lattice positions but auxiliary ACK (simple tokens of acknowledgement) travel from the other direction. This is different from the arrangement of sending all the co-ordinates to the ensemble at once, in that we add flow control. The step followed is given thus.

-The loading of position co-ordinates is done with the co-ordinates corresponding to least co-ordinates first and then moving on to higher position values in the ascending order.

-Since every module knows its position, when it gets the message with the same co-ordinate it "consumes" that co-ordinate.

-If the co-ordinate it gets is not the same as its position co-ordinate, then it simply acts as a transmission point and passes on the co-ordinate to its neighboring module.

-If same then after consuming the co-ordinate, the module gets activated and for the other co-ordinates it encounters it acts as a transmission point.



Completion of activation stage with all the appropriate catoms being activated

-The process continues till all the modules that form the part of the shape has been activated. Alternatively till all the co-ordinates have been loaded.

-As seen in fig2 during activation the position co-ordinates are transmitted through the modules like a "chain reaction". This process can never end. A possible solution is that each catom has a memory in that if a catom gets d same co-ordinate the second time it kills it.

At the end of the process the modules which belong to the shape will be activated. The next step in the process is shape formation. A plausible approach has been given below.

Formation

At this point in the process the modules will be activated, the activated modules will have to be bonded. The bonding has to happen between activated modules. Figure illustrates one possible way to do this.

Initially the device initiates the process of bonding by sending a simple initiation message. This occurs the instant when it receives the last ACK frame. The steps involved are given thus.

-The catom which first gets the message will transmit it to its nearest neighbors.

-If the neighbors are activated modules themselves, then it will bond to the catom from which it got a message through the contact patches/points [3]

-If the neighbors are dormant modules the message is simply ignored.

-The bonded module then transmits the message to its nearest neighbors. The whole process continues till all the modules are bonded thus the shape is acquired.

There is the possibility that an already bonded module can get the message again. In such a case the catom simply ignores the message. One more possibility is that a catom might get "bonding message" from two catoms at the same time. Under such a condition the catom can bond to all the catoms or acknowledges the message one by one and bonds to the catom with the smaller X/Y or uses simple math calculations(such as sqrt(x^2 + y^2) and bonds with the least resulting value. This process is illustrated in fig (3).

After the catoms have bonded, the remaining catoms which are not activated are just extracted from the ensemble to obtain the realization of the object by just the catoms. This is shown in the fig (4)

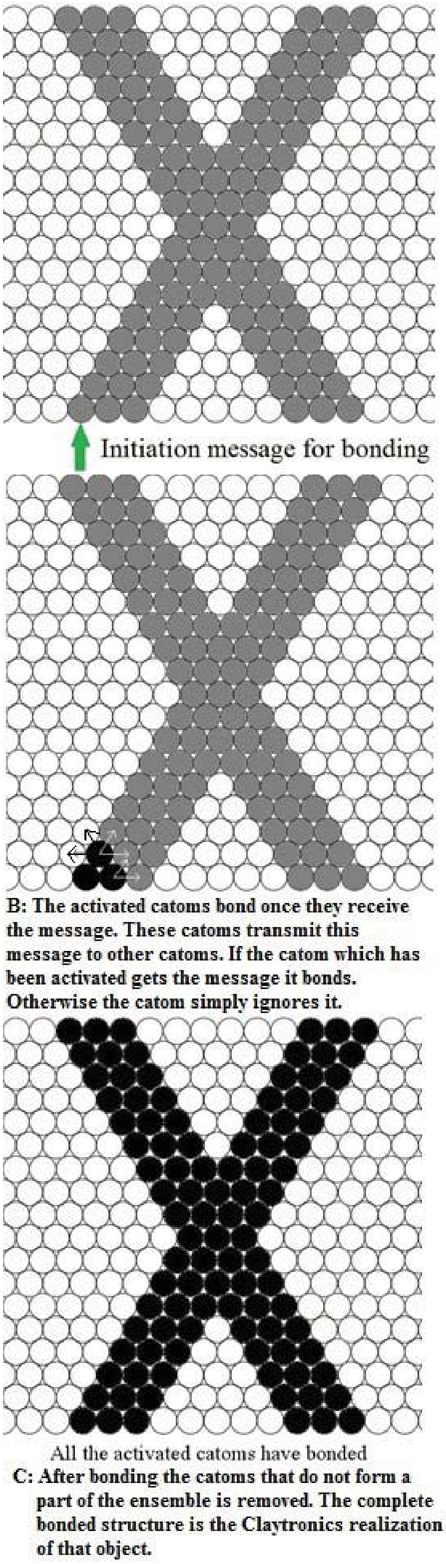


Fig (3)

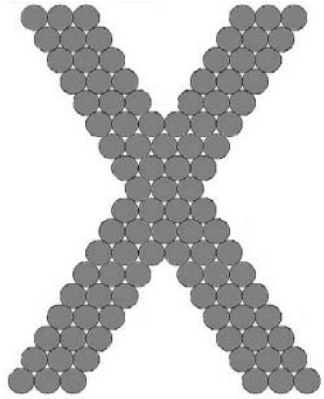

Fig (4)

IV. For 3-D Realization

The whole concept of claytronics can be extended to apply to 3-D objects as well. Here the catom ensemble is assumed to be 3 dimensional. It is also assumed that the computer knows all the coordinates of all the catoms. For image acquisition of a 3-D image, photographs of the object under consideration are taken from different angles. These photographs are then combined using sophisticated techniques to obtain a 3-D photograph of the object [10], [11]. More description of 2D to 3D conversion technique is beyond the scope of this paper. This 3-D image is compared with the ensemble and the coordinates of the catoms which are required are calculated and transmitted.

For shape reconstruction too, the ensemble is assumed to be 3 dimensional. Here the co-ordinates which are transmitted are input to the ensemble. The catoms belonging to the shape to be realized are activated in the same way as the 2-dimensional process. Applying the same principle of stop and wait protocol, the critical coordinates are fed to the ensemble one at a time, each time waiting for an ACK reply to confirm valid transmission. The catoms which aren't activated merely act like transmission paths and route the coordinates to its adjacent catoms. The activated catoms too act like transmission points for the other coordinates. After all the required catoms are energized, the activation stage is complete and the formation stage begins.

In the formation stage the actuation signal is input to a particular catom. This catom broadcasts the bond message to see which of its neighbors are activated. These activated catoms then bond. These bonded catoms individually broadcast the bond message to see which of its neighbors are activated and the process continues.

V. Scope for further development

There are several areas where improvement and research has to be done. In the two image acquisition techniques described, it might not be possible to acquire complete picture of the object and scale it down to the single catom scale. One possible solution may lie in advanced image acquisition techniques where each and every contour can be captured. The time delay involved in activation of certain catoms which are spread far and wide might has to be considered as it might not be insignificant. Efficient algorithms have to be implemented in such cases where the input signal is fed to many catoms instead of a single catom while at the same time achieving the desired result. The paper proposes a technique where the motion or orientation of catoms is not involved. This leads to significant advantages when it comes to power conservation but it might not be feasible in certain situations. For example 3-D realization of an abyss or any object with deep elevation changes, it would involve movement or removal of catoms from certain regions. Another constraint is it might not be possible to implement certain physical structures (for instance where much of the weight is concentrated on the upper half of the structure) with only the activated catoms. Some more additional catoms would also need to be activated to sustain the structure. This algorithm will work effectively for big 3-D realizations but for small 2-D realizations, hole motion algorithms can be used [4], [5]. When these considerations are incorporated into the algorithm, most of the limitations can be overcome and the algorithm would be effective in almost all situations.

Abstract: We study on an approach to teach a new action to a communication in spoken commands. It is supposed that these robots are used for household use. Usually, a spoken command corresponds to a predefined action in this type of system. However, it is difficult to prepare many predefined actions to meet user's expectations in any situations. In this paper, we proposed an approach to teaching a new action which is composed of basic actions through spoken commands. And also, we demonstrated our proposed approach through a communication robot PaPeRo, which has a speech recognition system in Japanese. In our experiment, it took approximately 50 seconds to instruct the five combinations of a basic action and an instruction modifier through 10 spoken commands. After teaching the new action, it took approximately 20 seconds to complete a series of stored actions through a single spoken word.

Keywords: Communication robot, speech recognition, teaching

1 INTRODUCTION

There are several researches on service robots communicating with people through spoken dialogue [1, 2, 3]. It is supposed that these robots are used for household use. In general, a spoken command corresponds to a predefined action in this type of system. It means that the robots can perform only a predefined action through spoken commands. Therefore the robots can serve in limited situations. However, a designer is very difficult to prepare many predefined actions in any situations. A user cannot adjust predefined actions without programming according to its expectations. Our solution to this problem is that a user can teach a new action to the robot according to its need. In this paper, we proposed an approach to teaching a new action which is composed of basic actions through spoken commands [5]. And also, we demonstrated our proposed approach through a communication robot PaPeRo [4], which is manufactured by NEC Corporation and has a speech recognition system and speech synthesis in Japanese.

2 OUR PROPOSED TEACHING SYSTEM THROUGH SPOKEN COMMANDS

Our basic idea is that a new complex action is composed of basic actions. It means that a user can teach a new action to a robot via spoken words which describe combination of basic actions. A simplest case is that a robot memorizes a sequence of basic actions. A more complex case is that a robot memorizes a sequence of basic actions and responses to some situations, where a robot is interrupted during acting. A much more complex case is that a robot communicates with a user and modifies apart of a memorized sequence. In stage of practical use, a robot needs to communicate with people via multimodal interfaces such as touch and vision in order to response to contacts with perople and to memorize people and places.

Our proposed teaching system is based on a speech recognition system and a learning system which can store a spoken word corresponding to a sequence of basic actions. Design of our system depends on implementation of the used robot, that is, PaPeRo. Therefore, our implemented teaching system is described in Section 3.

3 EXPERIMENTS

3.1 Overview

In order to perform preliminary experiments to evaluate our proposed approach, we defined the four basic actions (go forward, go backward, turn right, turn left) and the three instruction modifiers (small, middling, big), which specifies magnitude of travel distance or rotation angle in a single action. We prepared a program to store the five combinations of a basic action and an instruction modifier in the robot's memory and to play the new action through a single spoken command. After the robot accepted the spoken command for 'teaching a new action', it waits for a spoken command for basic actions. Next, the robot waits for a spoken command for instruction modifiers. For instance, when a user says, 'go forward', 'big', it means the robot travel long distance forward. Then, a user can give five basic actions to the robot. Here, limitation on the number of stored actions

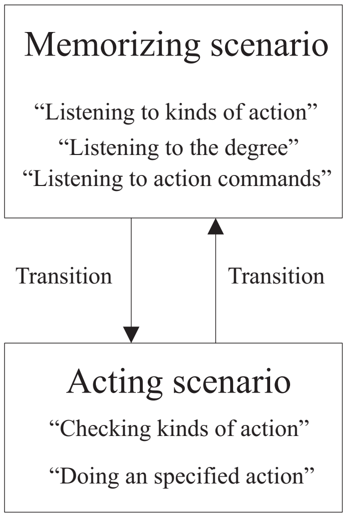

Fig. 1. The teaching scenario

is provisional for preliminary experiment and can be easily changed by modifying the program. After a user taught a new action, the robot can play the new action through a spoken command.

3.2 Experimental setup

PaPeRo has functions of speech recognition and speech synthesis in Japanese. In addition, PaPeRo has two active wheels for moving on a floor and several touch sensors and two cameras, which we do not use in this paper. PaPeRo acts according to a specific scenario, which describes its internal states, external events, robot actions, and state transitions, that is, a finite state machine. We described scenarios to memorize a sequence of basic actions and to invoke a new action. Fig. 1 shows a diagram of the teaching scenario consisting of the memorizing scenario and the acting scenario. In the memorizing scenario, a robot listens to kinds of basic actions and the degree, that is, the instruction modifiers. After memorizing a sequence of basic actions, a robot listens to action commands such as invoking a new action. The acting scenario is prepared in order to travel or turn the robot. The aim of separating scenarios is to remove complex commands to move the robot from the memorizing scenario.

Fig. 2 shows a flow chart of the memorizing scenario. In the memorizing scenario, a robot listens to a pair of kinds of basic actions and the degree until five times. After a robot listens to a pair, it performs an instructed. After a robot memorizes a sequence of the pairs, a robot listens to the action command "all" and performs a new action according to the memorized sequence.

Fig. 3 shows a flow chart of the acting scenario. In the acting scenario, a robot checks if a specified action is travelling or turning. The reason is that the travelling command and the turning command are not the same programmatically.

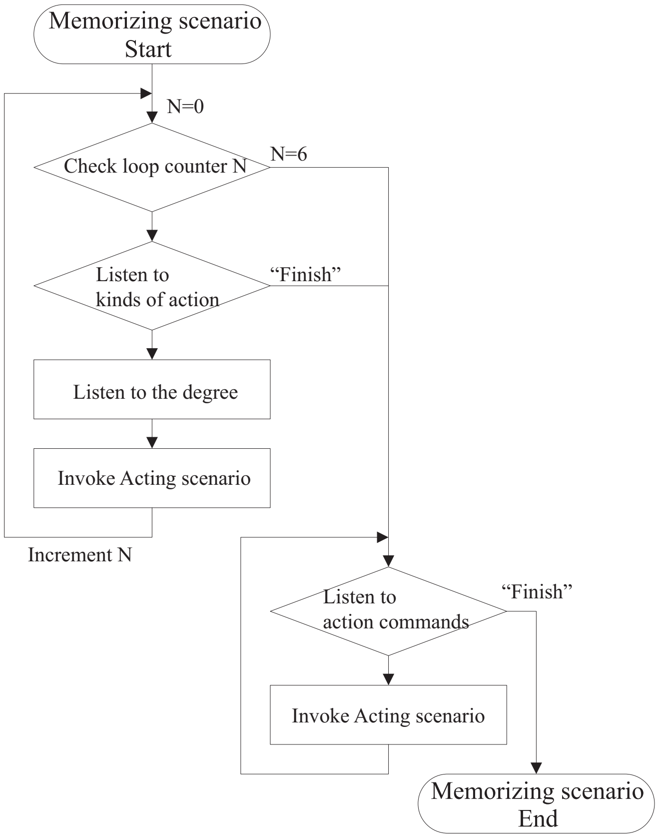

Fig. 2. The memorizing scenario

We defined pairs of a spoken command and a basic actions as shown in Table 1. Table 2 shows definition of instruction modifiers.

3.3 Experimental results

We demonstrated teaching of the new action to travel the robot along a route as shown in Fig. 4. Fig. 5 shows a time chart of our demonstration. We give five pairs of basic actions and instruction modifiers to the robot. The robot memorized the 10 spoken commands as follows:

1. "Go forward" and "ordinarily"
2. "Turn left" and "big"
3. "Go forward" and "big"
4. "Turn right" and "big"
5. "Go backward" and "ordinarily"

Note that a user actually spoke Japanese words in the experiment. After teaching, we give a spoken command "all" to invoke a new action according to memorized sequence of basic commands. A robot performed the new action successfully as shown in Fig. 6.

Table 1. Definition of basic actions

Spoken command	Definition
Go forward	A robot goes forward with constat speed for a specified period
Go backward	A robot goes backward with constat speed for a specified period
Turn right	A robot turns right in the center of its current position by specified rotation angle
Turn left	A robot turns left in the center of its current position by specified rotation angle

Table 2. Definition of instruction modifiers

	Duration [s]		Rotation angle [deg]	
	Go forward	Go backward	Turn right	Turn left
small	1	1	-30	30
ordinarily	3	3	-60	60
big	6	6	-90	90

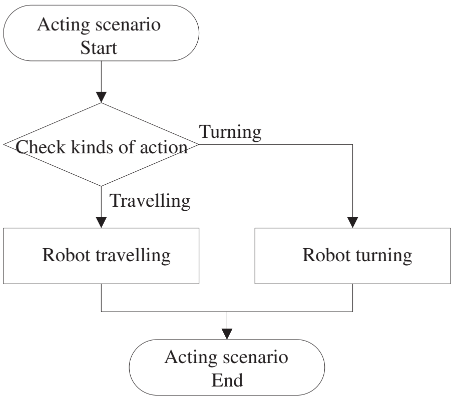

Fig. 3. The acting scenario

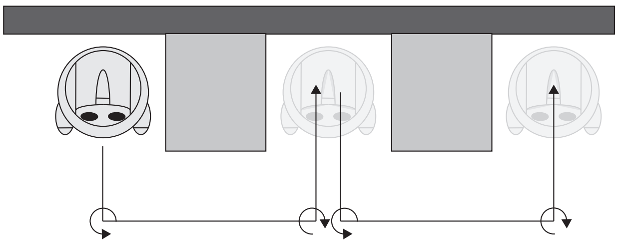

Fig. 4. The travelling route of the robot

In our experiment, it took approximately 50 seconds to instruct the five combinations of a basic action and an instruction modifier through 10 spoken commands. On the other hand, it took approximately 20 seconds to complete a series of stored actions through a single spoken command. We showed that our proposed teaching system realizes to teach a new action to the robot through spoken commands without developing a new program and that teaching a new action via spoken commands is useful for saving time and labor.

4 DISCUSSION

In our demonstration as mentioned above, a robot memorized a sequence of basic actions and instruction modifiers. It means that we realized a simplest teaching system mentioned in Section 2. In the demonstration, it is difficult for us to memorize 10 spoken commands. For instance, when the tenth command is spoken, it is hard for us to recall the first command because we cannot memorize too many commands at a time. Therefore, we need to confirm given basic actions until a certain point before completion of teaching. And also, when a user gives mistaken command to a robot, modification of a taught action is needed. In order to deal with these cases, we need to improve the teaching system as a user smoothly teaches a new action to a robot.

5 CONCLUSION

In this paper, we proposed an approach to teaching a new action which is composed of basic actions through spoken commands. A spoken command corresponds to a predefined action in conventional communication robots. We demonstrated our proposed teaching system through a communication robot PaPeRo, which has a speech recognition system in Japanese. In order to perform preliminary experiments, we defined the four basic actions (go forward, go backward, turn right, turn left) and the three instruction modifiers (small, middling, big). Our teaching system can memorize a squence of basic actions and instruction modifiers via spoken commands and invoke a new action after teaching.

In the future work, we will improve the teaching system in order to deal with modification of a taught action via spoken commands.

Abstract: This research considers the teleoperation of an articulated robot arm by means of force-free control and visual servo control over communication channels using Internet technology. The main investigation is carried out to find how effectively improves the accuracy and the effectiveness of the teleoperation after provision of a visual feed back channel to the system. The system accuracy, effectiveness, repeatability, and handleability based on the human operator's skills and operator's cognitive aspects are evaluated by using statistical data analysis and experimental results. Effectiveness of the statistical analysis is assured by increasing number of experiment data and assuming environmental factors and implicit variables maintain to be unchanged.

1 INTRODUCTION

In many years, telerobotics has been a major concern among researchers. It becomes more focused and justified for space and undersea operations, fire-fighting and rescue operations in battlefronts and disasters, and also for training and entertainment activities. Teleoperation is of utmost importance, when the working site is hazardous, such as nuclear plant activities, land-mine extraction, toxic chemical plant activities and so forth. In recent two decades, Internet has been much popular infrastructure for the communication activities and therefore, researchers use Internet for telerobotic applications as consistent communication platform. The TCP sockets have also been consistently used in many areas in telecommunication so that it gives past track records to be guaranteed as reliable communication with flow control, sequencing and re-transmitting of lost data [1]. The first Internet based telerobotics started as *Goldberg* [2] connecting a SCARA and ASEA IRb-6 type robots to the Internet in 1994. Since then, more researchers found their interest to use Internet for the development of advanced robot teleoperation applications, and remarkable early stage developments are published in [3], [4] and [5].
However, the major concern in Internet technology based teleoperation is that an uncertain transmission delay between human operator in the master side and the teleoperated robot in the slave side. Major contributions to overcome such transmission issues are given in [6]. The *Sheridan's* supervisory control [7] was proposed and it was appreciated in view of stable teleoperation. Supervisory control approach implements an autonomous local feed back loop at the slave manipulator. Remote human operator needs only to send key parameters or few required data to initiate and the slave manipulator, of what just slave manipulator required for planing the trajectories and controlling the manipulator. In this research is also based on a human supervisory control approach.

Figure 1 shows the schematic model representation of an Internet-based supervisory controlled teleoperation system. It also illustrates the main components and the terminologies in the context of a teleoperation systems. In our research, we adopted the same base architecture for experimental teleoperation setup. Moreover, the applicability and effectiveness of the supervisory control in teleoperation is highly depended and affected by the capability of the supervisory control in the master side as well as the local controller of the slave side. The investigation is based on the evaluation of the human operator's skills and cognitive factors on a supervisory control. And how those factors can correlate with an effectiveness of the investigated teleoperation system.

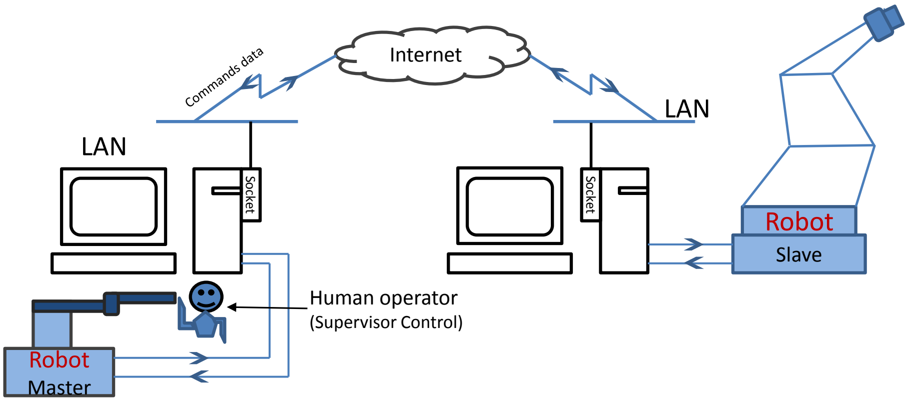

Fig. 1: Schematic diagram of general supervisory controlled semi-autonomous teleoperation system.

The teleoperation system of this research comprises of two different techniques which are attached in to different modules. First one is the force-free control (FFC) which is used to realize the passive motion of robot arm for given external force by human operator. The details of the FFC are described in [8] and references therein. The second one is the image processing module in which template matching (TM) techniques are used to carry out the accurate motion control by means of visual servo control [9]. Experiments were carried out by selecting operators appropriately corresponding to the following three kinds of experiments:

1. Providing camera view feedback to the operator.
2. Giving a guided map including desired path of the target.
3. Both map and visual feedback provided.
4. No additional aid provide (by seeing remote location robot from operational point).

2 TELEOPERATION BY FORCE-FREE CONROL AND VISUAL SERVO CONTROL

Our teleoperation system consists of two different motion control mechanisms. First is to accomplish remote control action by means of human operator assistance, in which FFC method is used. The details of the mechanisms and functions are described in author's work [10]. Figure 2 shows the detailed schematic presentation of the teleoperation system in this paper. The position control can be achieved by two kinds of motions for the reference position of the robot arm, i.e., the rough motion and the accurate motion. For the rough motion, the reference position is generated manually by using the FFC. Second is to accomplish the accurate motion where the reference position is generated automatically by using the vision system based visual servo control (VSC). In order to generate the reference position of the robot arm for the accurate motion, the image obtained from the USB camera is analyzed and processed. The vision system attached to the camera side is responsible for detecting the target position. The reference position data for the robot arm are sent through the network.

After receiving reference position data from the master control, slave robot in the working side moves accordingly as "rough motion." The human operator moves the master robot arm manually until the camera mounted on the working side robot captures the image of the target object. Then system switches to the second control scheme for "accurate motion."

2.1 Force-free control (FFC)

The FFC realizes the passive motion of the robot arm due to external force so that the robot arm can move freely according to the external force. In this teleoperation system FFC control plays an important role by generating reference positions when human operator executes the desired movement on the operational side robot. The generated reference position data is sent to the working side robot via network by using the socket communication TCP/IP [11]. The FFC for passive motion of the robot arm is applied without changes to the robot manufacturer's hardware configurations [12].

2.2 Visual servo control (VSC)

In our teleoperation system, VCS [9] plays an important role by helping working side robot arm to reach the target, after switching from the "rough motion." A general USB camera can be used in the VSC. At each sampling time, image is sent to the image processing in the camera side computer.

The image analysis is done by using template matching (TM) techniques [13, 14], in which, it calculates the position

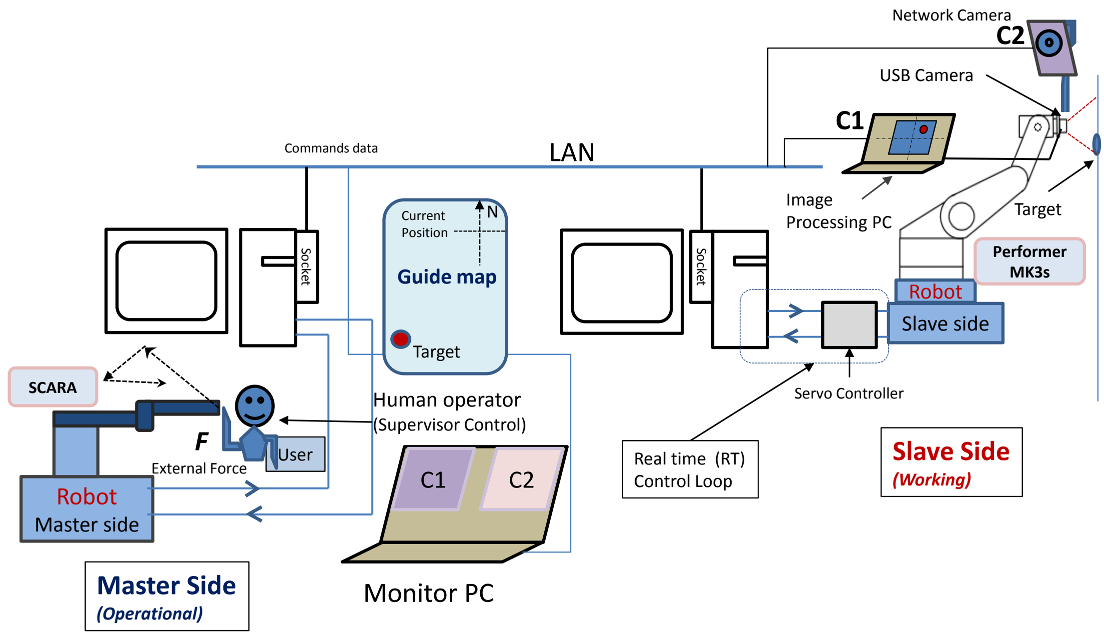

Fig. 2: Schematic overview of the investigated teleoperation system with visual feed back

of the target inside the image. Then, system calculates the corresponding reference position and send it to the working side robot. To apply the template matching algorithm, camera image must be processed at a each sampling so that, robot can reach to the target position. The center of the camera view and the target object at a particular instance of the VSC are calculated in each sampling. And continuously, image is processed and applied the template matching until target would coincides with the center of the camera view.

3 HUMAN OPERATOR'S PERCEPTION

The main objective of this research to investigate the applicability of the system by using different users and scenarios. Therefore, this research is focused on some aspects of the system especially for accuracy, effectiveness, repeatability, handleability and so forth.

In a practical situation no one can guarantee that high skill exclusive operator would be available in all time. Therefore, teleoperation system design is focused to make it as simple to operate even by the average user who does not have prior experience or special skills of operating the system. And also it can be operated with the minimum guidance as shown in Fig. 2. the system would provide the operational assistance by means of online camera views (C1 and C2 in Fig. 2) and the guide map of the target location.

The human operator's responsibility is to manipulate the robot arm in the operational side as to give "rough motion" to the working side robot that would catch the target within its camera view. To investigate the ability of applying the supervisory action by the general user, a larger number of experiments were carried out by providing different means of aid to human user and also sample of users were selected with irrespective of experience, age, field of studies and anthropometry of the body [15].

In general, each human has different levels of cognitive power, persistence, reactive or response time, level of skill for particular area, level of experience, prior knowledge of a particular subject etc. Therefore, any system with human involvement subjects to above mentioned aspects [16]. Due to above mentioned reasons, system is designed in such way that it should be identified the tolerances of those aspects if the system is intended to be applied in real practice.

4 EXPERIMENTAL RESULTS

Figure 2 is illustrated the experimental setup, the robot arm named Performer MK3s with attached USB camera in working side was controlled by the reference position generated in the operational side using SCARA robot. The SCARA is manually operated by a human operator until the target was included in the view of the camera. Then, Performer MK3s is controlled autonomously by the reference position generated in the camera side. As in the Fig. 2, target object is located in the slave side. A Network camera is used to capture the view of the target area and it will give the video feed back to the monitor PC as a camera view $C2$. The SCARA and the MK3s robots are connected to the computers in the master side and the slave side respectively. Image processing is done in the image processing pc $C1$ in the slave side of the system. The arrow marks are given to show the movements of the SCARA robot which are performed by a

human operator.

In this experiment, each of the experiments was done by volunteer users as listed in the table 1. The experiments were arranged to get four readings from each user. Users skill level is defined based on the past experience of using the system and ranked them as "High", "Low" and "New" as in the table 1. Four reading were taken form different scenarios of the experiments as listed in the table 1 as follows:

1. "Direct View" is given for an operator manipulate the robot arm by looking at the master side robot directly and no any other aid is given.

2. "Guide Map" is given for an operator manipulates the robot arm by only looking at the site map of the target position as shown in the Fig. 2.

3. "Camera View" is given for an operator manipulates the robot arm by looking at the computer monitor which has camera view of the target location of the working side as shown in the Fig. 2.

4. "Guide and Camera View" is given when operator has both aids of guide map and camera view feed back.

However, communication delays contracted in the system are assumed to be constant for all the scenarios and effects of them are not taken into the account.

The results showed that visual feed back improved the effectiveness of the total teleoperation cycle in regardless of the age and level of experience. However, communication delay on video stream can degrades the decision taking time for performing desired movements by applying external force. Statistical data analysis using the "probability and correlation coefficients" are carried out to verify the results based on how effectively target is reached on different experiment scenarios by different human operators as shown in tables 2 and 3. The "success level" gives the probability of success in each category.

To identify a feasibility of the use of the teleoperation system by different users with different perceptions, thorough investigation are carried out by using unbiased sample of human users. In this investigation, we used 26 different trials of experiments as given in table 1 which denotes the abstract and final information about the total investigation. User age and user's field of studies whether it related to the teleoperation or not are also given under remarks. From the research, We draw main objective that how effectively new user having different perspectives can operate the teleoperation system by using different visual aids such as a video feed back or/and a guide map of the target location.

In addition, a new user was given an introduction prior to begin his trials of experiment. It was found that certain either new or experience users shown energetic and confident interest, and also they wanted to perform more and more trials, however, few of them were found an uncomfort feeling and were lethargic during their turns. Hence, the effectiveness of the supervisory action also depends upon operators instantaneous condition and cognitive aspects of their mind or/and their perspectives regardless of their experience or skills at the time of an experiment [17].

Table 2: Correlation variations with skill level

	Category	Correlation with skill level	Remarks
1	Direct View	-0.2218	Negative
2	Guide map Only	0.1379	Positive
3	Cameras Only	-0.1011	Negative
4	Cameras & Guide	-0.1136	Negative

Table 3: Probability of success variation with category

	Category	Success level %	Remarks (Skilled user)
1	Direct View	80.77	all success
2	Guide map Only	42.31	2 failed
3	Cameras Only	73.1	2 failed
4	Cameras & Guide	88.46	all success

5 DISCUSSION

According to the table 2 guide only scenario is shown positive correlation with skill level. However, all other scenarios, correlation with skill level and success rate have negative correlation. Also it is observed that negative correlation decrease with introduction of camera view, this indicate giving online visual feed back with instruction to the users give better performance. And also introduction of a camera view, it increases the correlation coefficient value between skill level and success rate. Table 3 shows the success probability variation for an each category. Results show that positive increment on a system effectiveness by introducing online camera feed back regardless of a user being an experienced or not. However, experienced users of the system show characteristics that they can handle the system successfully even without an online visual feed back. Moreover, certain amount of users who found difficult to use and manipulate the teleoperation system and results show that success percentage varies when category changes. It is also observed that some users could not be able to manipulate the system in a way that the working robot on desired rough motion towards the target. However, in their second attempt, same users could get succeeded. Therefore, we conclude that system operational functions can easily be understandable for a general user who did not have either any previous interactions or experience on using the system. Since, the sample of users is used for the investigation does not include female users, correlation results might have a high possibility of variation if sample includes female users.

6 CONCLUSION

In this contribution, an investigation is carried out for the teleoperation system to find out how human factors with cognitive aspects affect the system effectiveness and performance when it applies in practice. It is essential that we must test the system with large number of real scenarios to validate the applicability, if the teleoperation system claims to be used in real application. Moreover, especially if a system has human user involvement and which is a critical factor for a fulfillment of final objectives then a sample of users should be selected with a high degree of variation and a sample amount must also be higher. The relevance of the real world application of the teleoperation system, particularly in case of human supervisory involvement, is highlighted from this paper. Finally, by providing a visual feed back for the human user effectively increases an applicability and an effectiveness of the teleoperation system regardless of users' skills, age and relevance to their major field of study. By considering the results, if the user sample number increases nearly up to 100 then, regression analysis can be carried out by using a fitted model for the experimental results.

Abstract: In this study, we develop flexible joints for a humanoid robot that walks on an oscillating plane and discuss their effectiveness in compensating disturbances. Conventional robots have a rigid frame and are composed of rigid joints driven by geared motors. Therefore, disturbances, which may be caused by external forces from other robots, obstacles, vibration and oscillation of the surface upon which the robot is walking, and so on, are transmitted directly to the robot body, causing the robot to fall. To address this problem, we focus on a flexible mechanism. We develop flexible joints and incorporate them in the waist of a humanoid robot; the experimental task of the robot is to walk on a horizontally oscillating plane until it reaches the desired position. The robot with the proposed flexible joints, reached the goal position despite the fact that the controller was the same as that used for a conventional robot walking on a static plane. From these results, we conclude that our proposed mechanism is effective for humanoid robots that walk on an oscillating plane.

Keywords: Humanoid Robot, Flexible joint, Elasticity

1 INTRODUCTION

In this study, we develop flexible joints for a humanoid robot that walks on an oscillating plane, and discuss their effectiveness in compensating disturbances. In conventional studies, robots have a rigid frame and are composed of rigid joints driven by geared motors. Therefore, disturbances, which may be caused by external forces from other robots, obstacles, vibration and oscillation of the surface upon which the robot is walking, and so on, are transmitted directly to the robot body, causing the robot to fall [1]. To prevent falling, conventional robots require various sensors and a high-spec controller for real-time processing [2]. Nevertheless, it is very difficult for the robot to react quickly and avoid a fall, which prevents robots from operating in unknown dynamic environments. To address this problem, we focus on flexible mechanisms. A flexible mechanism can adapt itself to a rapidly changing environment passively because of its dynamics and physical properties [3-5]. In addition, it requires no sensors and no controllers, because the necessary information is contained within the mechanism itself and the calculation for its control is implicitly performed by its dynamic and physical properties. In our previous study, we developed and confirmed the viability of a flexible joint whose elasticity can be adjusted to adapt to a dynamic environment. The flexible joint presented here compensates for disturbances passively, reducing the load of the controller [6]. However, the previous study was focused on the effectiveness of the flexible joint itself and the performance of the entire robot was not sufficiently discussed. In particular, the subject of autonomous control that would enable a robot to move to a desired position was not addressed.

In this study, we address the topic of autonomous walking by a robot to reach a desired position. We improve our previous flexible mechanism [6], and we develop a humanoid robot that can walk on an oscillating plane to reach a desired position by using a simple autonomous controller that is actually designed for walking on a static plane.

2 TASK AND ENVIRONMENT

For experiments on an oscillating plane, we employ a vibration generator, as shown in Fig.1. The environment measures 1000 mm × 1000 mm. The oscillation amplitude is 50 mm, and, to confirm the frequency response, we vary the frequency from 1.5 Hz to 5.0 Hz.

The task of the robot is to walk toward a target position on the oscillating plane.

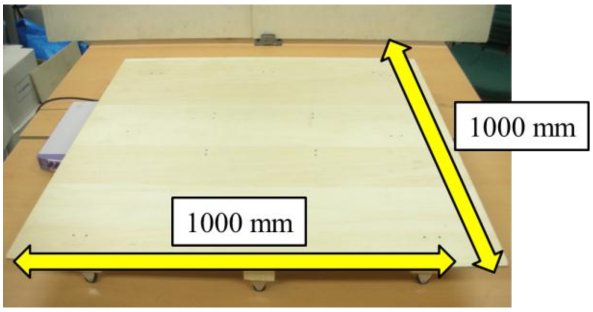

Fig. 1. Oscillating Plane

3 FLEXIBLE JOINT

Fig. 2 shows an illustration of the flexible joint [6]. An upper link and a lower link are brought into contact through the ball bearing and a rubber band. It is possible to for them to interact through the rubber band. If the upper link slides, the rubber cord is pulled and the upper link is pulled back. The length of rubber cord can be adjusted with the servo motor, which causes the rigidity of the flexible joint to change.

Due to the viscoelasticity of rubber, the flexible joint has the characteristics of a low-pass filter. This implies that high-frequency oscillations are removed on account of its dynamic properties.

4 DEVELOPED ROBOT

4.1. Humanoid robot

Fig. 3 shows our previous robot [6], and Figs. 4 to 6 show the robot that we discuss in this paper, and Table 1 lists its specifications. In our previous robot, two flexible joints are embedded in each leg, increasing the complexity and the weight. In particular, increase of the legs' weight causes a decrease in the robot's mobility. In this paper, we improve these issues by embedding two flexible joints in the robot's waist. By this mechanism, we reduce the number of the flexible joints and can employ legs with both a simple design and high mobility.

As shown in Fig. 5, the two flexible joints in the robot's waist are at right angles to each other, and can handle two-dimensional horizontal oscillation.

A CCD camera for detecting a target position is installed in the robot's head, and a micro-computer for controlling the servo motors is mounted on the body.

Width	180 mm	Actuator	KRS-4034HV, KRS-788HV
Depth	130 mm	Degree of freedom	16

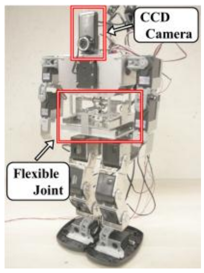

Fig. 4. Humanoid robot

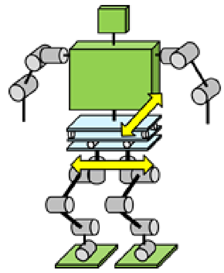

Fig. 5. Sliding direction of the flexible joints

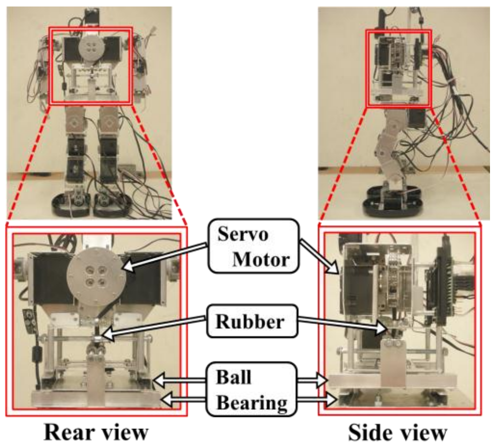

Fig. 6. Developed flexible joint

4.2. Adjustment of the spring constant

Fig. 6 shows the developed flexible joint. The pulling force of the rubber in the horizontal direction F can be approximated by equation (1). As shown in Fig. 7, the elasticity (k of equation (1)) of the flexible joint can be adjusted by rolling up the rubber band through use of the servo motor.

From preliminary experiments, the relation between k and the angle of rotation of the servomotor was given by Fig. 7, and it can be approximated by equation (2).

$$F = -kx \quad (1)$$

$$k = 0.36\frac{\theta}{\pi} + 0.15 \quad (2)$$

k : Constant of spring [N/mm]

θ : Angle of rotation of the servo motor [rad]

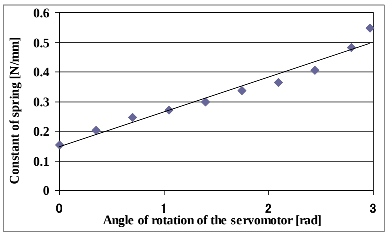

Fig. 7. Constant of spring

4.3. Frequency response of the flexible joint

The motion equation of a flexible joint is shown by equation (3). The frequency response of the flexible joint is shown in Fig. 8. The dotted line represents a high-elasticity (k = 0.50) joint and the solid line represents a low-elasticity (k = 0.15) joint. The cut off frequency of the high-elasticity joint is 7.7 Hz, and that of the low-elasticity joint is 3.7 Hz.

$$M\frac{d^2x}{dt^2} + D\frac{dx}{dt} + kx = f \quad (3)$$

M : Mass [kg]
D : Viscosity resistance [Ns/m]
k : Constant of spring [N/mm]
f : External force [N]

Table 2. Value of parameters

M	D	k (low)	k (high)
0.88 kg	1.00 Ns/m	0.30 N/mm	1.00 N/mm

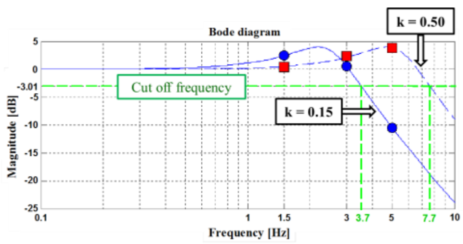

Fig. 8. The frequency response of a flexible joint

5 EXPERIMENT

To demonstrate the effectiveness of the proposed flexible joints, we conduct two experiments. In one experiment, the robot has to stand still on a horizontally oscillating plane, and in the other, the robot is required to walk on the oscillating plane toward a red colored moving target. The target is sensed by a CCD camera, and its image is transmitted to a PC, as shown in Fig. 9. The control signal that causes the robot to start moving to the target is generated by the PC and is transmitted to the micro-computer. The micro-computer generates walking behavior on the basis of the transmitted control signal and the already programmed walking patterns designed for static surfaces. The important point to note is that the oscillation of the surface is not measured and only the walking patterns for a static surface are employed. The oscillation is compensated for by the flexible joints, and hence, the load of the controller is reduced.

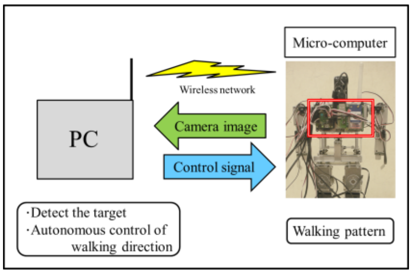

Fig. 9. Intercommunication network

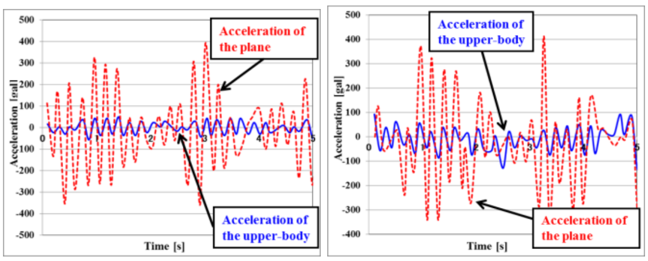
5.1 Experimental Results when the robot stands still

Fig. 10 and Table 3 show the experiment results of standing still. In Fig. 10, the solid line shows the acceleration of the upper body and the broken line shows the acceleration of the plane. Table 3 shows the ratio of the amplitude of the oscillation of the upper body to the amplitude of surface oscillation. From Table 3, we see that sympathetic vibration occurs when the spring constant is low, leading the robot to fall at a frequency of 1.5 Hz. However, the surface oscillation is absorbed when the spring constant is low in cases of higher frequency oscillation, and the oscillation of the upper body of the robot is decreased.



(a) Side to side (b) Front to back

Fig. 10. Result of acceleration (5.0 Hz, k = 0.15)

5.2 Result of the experiment where robot moves to target position

Fig. 11 shows an example of the result. In the case where the constant of the spring is low (k = 0.15), the robot could walk on the oscillating plane and move to the target. On the other hand, in the case where no flexible joints are present (all joints are fixed), the robot falls.

Table 3. Ratio of amplitude (Maximum acceleration of upper body [gal] / Maximum acceleration of ground [gal])

	1.5 Hz		3.0 Hz		5.0 Hz	
	side to side	front to back	side to side	front to back	side to side	front to back
fixing	36 / 36	36 / 36	falling	falling	falling	falling
k = 0.50	38 / 36	38 / 36	falling	falling	falling	falling
k = 0.23	falling	falling	60 / 146	93 / 150	102 / 405	184 / 394
k = 0.15	falling	falling	73 / 148	117 /153	56 / 393	93 / 414

From these results, we can confirm that the developed flexible joint has the characteristic of a low-pass filter, and due to this characteristic, the robot can move to the goal position on the oscillating plane without controllers for handling the oscillation.

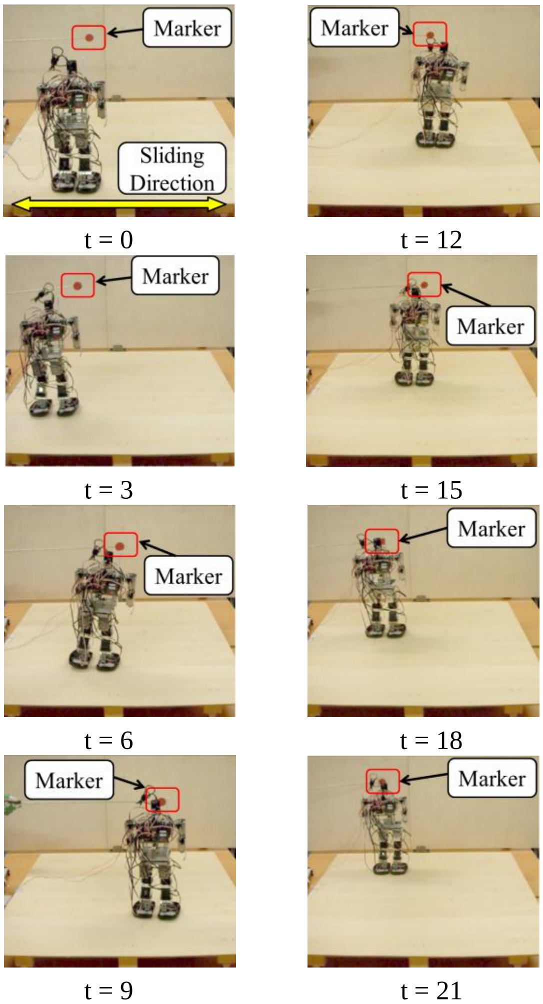


Fig. 11. Walk on the oscillating plane (5.0 Hz, k = 0.15)

6 CONCLUSION

In this study, we developed flexible joints for a humanoid robot that walks on an oscillating plane. By incorporating the flexible joint into the waist of a humanoid robot, we made it possible for the robot to move toward a goal position on a horizontally oscillating plane.

To demonstrate the effectiveness of the developed flexible joint, we conducted two experiments, in which effective walking behaviors were observed.

MANUALLY CONTROLLED MANHOLE CLEANING ROBOTIC SYSTEM

Gopal Joshi, Animesh Rana, Venkateshwar.R,
SCHOOL OF ENGINEERING,

VELS UNIVERSITY, CHENNAI, INDIA.

Abstract- ***Aimed at tackling the disadvantages of conventional manhole a new manually controlled manhole cleaning robot system is proposed for performing cleaning work instead of human cleaning manholes that is characteristic of low safety, low efficiency, long time and environmental pollution problems. The robotic system consists of manually controlled suction pump, hydraulic pump station, probe controller, LCD screen for monitoring; windlass, biodegradable bags, disinfectant sprayer. The modular structures have been adopted in the robotic system, which makes it possible to assemble all subsystems in a single unit. This robotic system can reduce the complex mechanism for cleaning the manholes and even provide environmental friendly way of disposing the sludge.***

Keywords: Manually controlled, Eco-friendly, Easy disposal, Safer, Easy use.

I. INTRODUCTION

The basic need of this robotic system is to clean the sludge from manholes. In most of the countries these manholes are being cleaned by humans who put themselves into greater degree of risks. The need of a robotic system which replaces human from cleaning job is quite high in many in most of the countries. This manually controlled robotic system will not only reduce the degree of risk for the people who are associated with this cleaning work but will also provide an eco-friendly way of managing and decomposing these biodegradable wastes. This will minimize the human interference in cleaning work and will make it more safer and easier way of cleaning manholes. It is similar to the systems that are used in cleaning oil tank [1]. The cleaning mechanism used here differs from the conventional oil tank cleaners. The technology proposed here is eco-friendly way of treating the sludge from the manholes which makes this robotic system more reliable and practically feasible.

Fig.1: The above figure shows the basic way cleaning manholes i.e. man entering the manhole risking his life and subjecting him to many bacteria and viruses present in these sludge.

II. SYSTEM REQUIRMENT

In this section, we will review the requirement of manhole cleaning robotic system. Major problem associated with cleaning this manhole is the size of this manhole. The radius of these manholes is extremely small which makes it very difficult for human to go in and clean thus causing injuries. The other problem is people cleaning this manhole come in direct contact with the harmful viruses present in the sludge. All these leads to the requirement of the manually controlled robotic system that helps in solving these mentioned problem and many other problems associated with it.

This manually controlled robotic system works on basic principle suction technique using suction pumps [2], this suction pump induces high pressure inside the manholes breaking the larger particles that are sucked using this induced pressure mechanism. The entire component used in this manually controlled robotic system works on advanced lithium-ion solid polymer electrolyte batteries [3], these high power batteries can be used for portable electronics applications [3]. It consists of touch screen LCD display device which performs dual function of controlling each and every component involved in the working of this system and for keeping track on all the function undergoing in the system. When the power supply is applied to the system, the system gets switched ON and all the controlling features appears on the LCD display. With the help of these controlling features manhole cleaning process is initiated.

There is another problem associated with this manhole cleaning process is proper and eco-friendly method of decomposing this sludge. This sludge from manholes are either dumped in rivers polluting the water body or burning these sludge in open ground causing air pollution and other environmental problem. In order to overcome this problem this robotic system is provided mechanism in which bio-degradable bags are used to fill all the sludge and later these bio-degradable bags are disposed [4] using various disposing methods. These biodegradable-bags are kept in the form rolls, when the controller starts suction process all the sludge from the manhole is sucked and starts filling in these bio-degradable bags. The sludge filled bags are then sealed. As soon as one bag is filled and led out the probe present in the robot pulls out another bag. When cleaning process is completed all sludge filled bags are disposed accordingly.

III. System Overview

A. *Power Source*

The power source which can be used is advanced lithium-ion solid polymer electrolyte batteries [3][6]. These new batteries will utilize new high-energy density anode and cathode active materials developed by SNL and RTI. UBI will incorporate these new materials into an optimized Li-Ion SPE electrode laminate [3].

B. *Suction pump*

The pressure of the suction pump can be manually adjusted according to the requirement. This suction pump works on the mechanism of producing air pressures and absorbing the target [2][6].

C. *Bio-degradable Bags and decomposition*

The purpose of using bio-degradable bag is to reduce pollution, ease the disposal work, prevention of unwanted manual labor. The main material starch and plant fiber for produce the dishware is analyzed in these bags. Biodegradable material is a kind of Green material, which is easily reclaimed and reused, it does not pollute the environment, and it can decompose quickly, there is not insurant to produce after trash [4][6].

Fig.2: Bio-degradable bag roll.

D. *LCD Controller And Display*

The LCD display unit and controller is fixed on the handle bar of the robotic system. This touch screen LCD device has pre-installed application which is used to control all the functional unit of this robotic system.

IV. *Evironment Benefits Of Bio-Degradable Bags*

Biodegradable bags from natural materials, such as vegetable crop derivatives or animal products, sequester CO_2 during the phase when they're growing, only to release CO_2 when they're decomposing, so there is no net gain in carbon dioxide emissions. Under proper conditions biodegradable plastics can degrade where microorganisms can metabolize them.

V. Manually Controlled Manhole Cleaning Robotic System

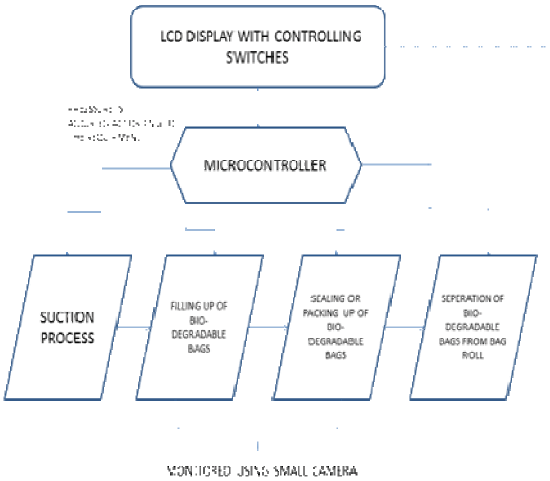

Fig.3 Schematic diagram of working process

VI. Working

The working process of this manually controlled robotics system is done by operator. All the components are controlled by application that can be accessed using touch screen LCD device which is connected to each component. Small camera is fixed inside the circuitry through which entire process can be seen on LCD display. This will help the operator to keep the check on all the process taking place inside the system.

Following process takes place in this system:

A. *Suction process*

*When t*he operator applies the power sources, the suction pump with adjustable pressure gets switched ON and the suction pipe is inserted into the manhole [6]. This inserted suction pipe creates pressure inside the manhole to be cleaned. The smaller sludge particles are easily sucked but it is really difficult to suck relatively larger sludge particle. As this suction pump is provided with adjustable pressure range mechanism, high pressure is induced inside the manhole. Due to this high pressure the larger sludge particles blocking the manholes are disintegrated into smaller particles. These disintegrated particles are then easily sucked by this mounted pressure. The operator continues this process until all the sludge from the manhole is sucked.

B. *Filling process*

The operator then starts the filling process, using two probes bag is pulled from the provide roll of bio-degradable bags. The sludge that is sucked using suction pump is then filled into these bio-degradable bags. These bio-debags are used because it is easy to decompose and environment friendly method of disposal of the sludge. The usage of these bio-degradable bags prevents the disposal of sludge [6] into water bodies or burning them in open ground effecting environment.

C. *Sealing process*

After the sludge is being filled in the bio-degradable bags, the operator switches on the sealing process. In this process, when the bag is completely filled with the sludge it[6] is sealed and lead out.

D. *Disinfecting process*

The robotic system is provided with another section known as disinfecting section. In this section when cleaning process is performed completely some amount of disinfecting chemical is sprayed into the manhole. This sprayed chemical disinfects the manhole.

VIII. PROPOSED MANUALLY CONTROLLED ROBOTIC SYSTEM

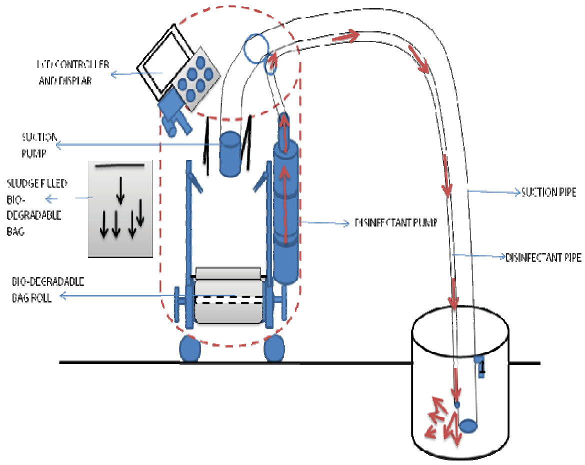

Fig.4 Proposed manually controlled robotic system.

VIII. PROCESS OVERVIEW

In this section the diagrammatical working mechanism of the manhole cleaning process is shown.

IX. Conclusion

In this paper we discuss about the use of robotic system to clean manhole. The use of this system will not only make this work simple but it will eco-friendly and safer for the people associated in this cleaning process. Future technologies can make it even more simple and easy to use.

X. FUTURE WORKS

In this paper we have proposed the idea of manually controlled robotic system. We are preparing the prototype of this manually controlled robotic system. Automated version of this robotic system will be done our future work.

Abstract: An improved Bug-type navigation algorithm that ensures convergence is proposed in this paper by integrating more heuristic information abstracted from the range data in the authors' previous work. While some similar concepts have been proposed before, the improved algorithm has fully considered many implementation issues that are ignored in the related works and therefore it is more practical than these works. Simulations show that compared with the authors' previous work, the improved algorithm can generate shorter average path length. Experiments on a real robot further verified its practicability.

Keywords: mobile robot; navigation; Bug algorithm; range sensor

1 INTRODUCTION

Autonomous navigation is an important research topic in mobile robotics. In many applications, the workspace is previously unknown and the robot has to utilize the sensory data to decide its motion, which significantly increases the difficulty of navigation. A common problem of many sensor-based navigation algorithms is that the robot may be trapped before reaching the goal when it encounters obstacles with complex boundaries, which is usually termed the local minima problem [1], [2]. Many efforts have been made to solve this problem and a well-known concept is the Bug model [3] which is focused on in this paper.

In the Bug model, the robot is assumed as a point moving in a 2D plane and it has only two motion modes: moving toward the goal and boundary following. It has been proved that if the switching criteria between the two modes are properly designed, the robot can converge to the goal as long as the goal is reachable (otherwise it will report failure). Due to its simplicity and convergence proof, the Bug model has attracted much attention. A series of algorithms have then been proposed based on this model, and they are often termed the Bug algorithms [4]. However, most existing Bug algorithms mainly focus on designing the switch criteria to ensure convergence and optimize the path, but ignore the implementation issues. As a result, the applicability of the algorithm may be affected. Focusing on this problem, we have proposed a new Bug-type algorithm in [5]. This algorithm presents not only a group of new switch criteria, but also a control strategy to implement it on real robots. The control strategy is also valid for many other Bug algorithms. Furthermore, it can generate shorter path than some previous Bug algorithms.

In this paper, the aforementioned algorithm (it is termed the original algorithm below) is further improved by integrating more heuristic information abstracted from the range data to optimize the generated path. The remainder of this paper is arranged as follows: related works are briefly reviewed in Section 2; our work is presented in Section 3 and the experimental studies are presented in Section 4.

2 RELATED WORKS

Since most Bug algorithms can ensure convergence, their performances mainly differ in the path length. Hence how to shorten the generated path is the main problem discussed in most previous works. The most common strategy is to design new switch criteria and our previous work [5] followed this way. Another method is to bypass the obstacles in advance by exploiting the sensory data. This idea firstly appeared in the VisBug algorithm [6], which improves the classical Bug2 algorithm [3] by using range data to find shortcuts of the original path. Based on a similar concept, TangentBug [7] constructs a "local tangent graph" based on the range data in every control cycle to guide the robot. Undoubtedly, exploiting the sensory data is beneficial to navigation. However, these two algorithms assume that any obstacle boundary can be continuously detected. Actually, due to the limited angular resolution, the practical range sensors can only detect the nearest obstacle point in a sector as shown in Fig. 1. Hence it is difficult to well realize these two algorithms since identification errors may occur [4], [8]. In this paper, a concept similar to

VisBug and TangentBug is proposed and integrated in our previous works to further improve its performance. A significant difference is that the angular resolution problem and many other implementation issues have been fully considered in the improved algorithm.

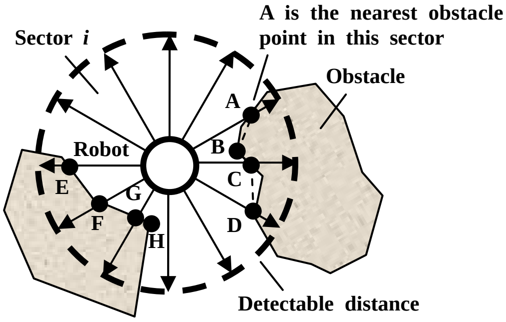

Fig. 1. The angular resolution of the practical range sensors: the robot can only detect eight obstacle points but not two continuous boundaries.

3 THE IMPROVED ALGORITHM

The improved algorithm consists of two reactive motion modes: moving toward the goal (Mode 1) and boundary following (Mode 2). They are respectively described below.

3.1 Motion toward the Goal

In Mode 1, the motion direction is selected by two steps. First, a rough direction θ_R that may lead to an optimal path is selected based on heuristic information abstracted from the range data. Then an exact direction θ_E for obstacle avoidance is calculated based on θ_R. Note that all the angles in this paper refer to the robot-fixed coordinates where the current robot direction is 0° and the angle increases in the anticlockwise direction.

In the first step, the key issue is how to abstract useful heuristic information from the range data. Assumed that the detectable view of the robot is divided into N sectors due to the angular resolution of range sensors as shown in Fig. 1 and each sector is labeled by an integer (a specific sector can be labeled as Sector 1 and the integer increases in the anticlockwise direction), an index set I that contains useful heuristic information can be defined as

$$\left\{ i \mid d_i \neq L \wedge (\left\| \mathbf{O}_i - \mathbf{O}_j \right\| \geq 2(r+D) \vee d_j = L) \wedge d_i < d_j \right\}$$
$$1 \leq i \leq N,\ j = \begin{cases} (i-1) \vee (i+1) & 1 < i < N \\ N \vee (i+1) & i = 1 \\ (i-1) \vee 1 & i = N \end{cases} \qquad (1)$$

where "$\vee$", "$\wedge$" are "logic or" and "logic and", $\mathbf{O}_i$ and d_i are respectively the position of the nearest obstacle point in the i^{th} sector and the distance to this point, r is the robot radius, D is the predefined safe distance to obstacles, L is the detectable distance (if there is no obstacle in the i^{th} sector, $d_i = L$). I contains the indexes of the key obstacle points which are the endpoints of the gaps between different obstacles, e.g., the point A, D, E, H in Fig. 1. A, H are termed "left jump point" and D, E are termed "right jump point". As shown in Fig. 1, if the goal is located in the gaps, the robot can approach it directly. If the goal is located behind any obstacle, the directions of the key obstacle points correspond to the shortest path for bypassing the obstacle.

Based on the above concept, only the goal direction θ_G and the directions indexed by (1) are considered as candidates for θ_R. However, three practical issues should also be considered. First, it is not safe to directly moving to a key obstacle point. Second, it is not wise to select a direction whose corresponding gap is not wide enough to go through. Third, the possible errors caused by the angular resolution and sensor inaccuracy should be considered.

To solve the first problem, the directions indexed by (1) are slightly revised by

$$f(\theta_i) = \begin{cases} \theta_i + \Delta\theta_i & \left\| \mathbf{O}_i - \mathbf{O}_j \right\| \geq 2(r+D) \vee d_j = L \\ \theta_i - \Delta\theta_i & \text{otherwise} \end{cases}$$
$$j = \begin{cases} i+1 & i < N \\ 1 & i = N \end{cases}, \Delta\theta_i = \begin{cases} \arcsin(\dfrac{r+D}{d_i}) & d_i > r+D \\ \arctan(\dfrac{r+D}{d_i}) & d_i \leq r+D \end{cases} \qquad (2)$$

where θ_i is the original direction indexed by (1). An example is shown in Fig. 2. Such a revision can guide the robot to smoothly bypass an obstacle.

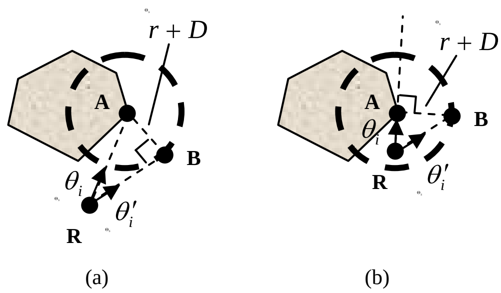

Fig. 2. An example of revising the directions (R is the robot center; A is a right jump point and therefore the direction should be decreased): (a) $d_i > r + D$; (b) $d_i \leq r + D$.

To solve the second problem, a precise method requires expensive computations. Hence a rough method is proposed: if there is no obstacle in a zone near the selected direction, the gap corresponding to this direction is considered as wide enough to go through. An example is shown in Fig. 3.

As to the third problem, due to the angular resolution, the relative position between the robot and the obstacle will affect the judgment of whether an obstacle point is a jump point indexed by (1). As an example shown in Fig. 4 (θ_0 is the minimal detective angle), the robot is initially at R_1 and it judges that B is not a jump point since D_1 is short. However, assumed that the robot moves to the jump point A, when it reaches R$_2$, B may be misjudged as a jump point since D_2 is long enough. Then the robot may move to B, which will cause a zigzag path. To solve this problem, it is required that if the robot selected a left (right) jump point as θ_R in the last cycle, the jump point will be recorded and in the current cycle, the robot can only select θ_R in the left (right) half-side of the vector from the current robot position to this jump point, i.e., the "admissible half-side" shown in Fig. 4. In Addition, the sensor inaccuracy sometimes also affects the judgment. Hence another constraint is added: if the robot selected a left (right) jump point in the last cycle, it cannot select a right (left) jump point in the current cycle unless it have attempted to select right (left) jump point in five successive cycles (one cycle is about 100ms in our experiments).

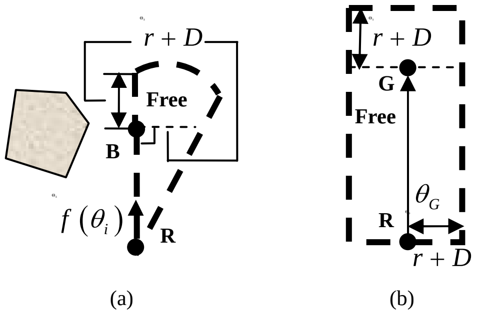

Fig. 3. An example of roughly examining whether a gap is wide enough to go through (B is the same point as shown in Fig. 2; R is the robot center; G is the goal): (a) if the direction is indexed by (1), the examined zone is a sector on the opposite side of the corresponding obstacle; (b) if the direction is the goal direction, the zone is a rectangle.

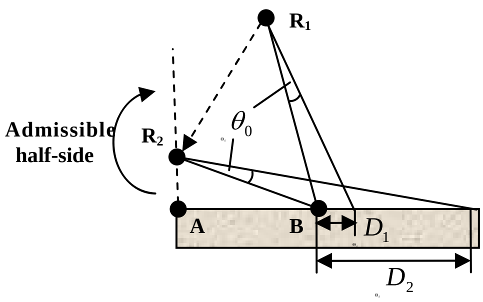

Fig. 4. An example of the misjudgment caused by the angular resolution.

Considering all the issues discussed above, θ_R is finally calculated by

$$\theta_R = \begin{cases} f\left(\theta_{i_0}\right) & I_S \neq \varnothing \wedge \mathrm{C}_1 \\ f\left(\angle\overrightarrow{RO}\right) & I_S \neq \varnothing \wedge \overline{\mathrm{C}}_1 \end{cases}, i_0 = \underset{i \in I_S}{\arg\min}\left\{\left|\theta_i - \theta_G\right|\right\}$$
$$I_S = \left\{i \mid W_i \subset W_{free} \wedge \left|f\left(\theta_i\right) - \theta_G\right| < 90^\circ, i \in I \cup \{N+1\}\right\}$$
$$f\left(\theta_{N+1}\right) = \theta_G, W_{N+1} = W_G \tag{3}$$

where $\angle\overrightarrow{RO}$ is the angle of the vector from the current robot position to the last jump point that has been used as θ_R, f is the map function described in (2), W_i, W_G are respectively the corresponding zone of θ_i and θ_G as shown in Fig. 3, W_{free} is the free workspace, C_1 is satisfied if any following event occurs: i_0 in the current or last cycle indexes the goal direction; both i_0 in the current and last cycle index left or right jump point; no above event has occurred in five successive cycles including the current cycle. In addition, if $I_S = \varnothing$, which implies that there is no collision-free direction for approaching the goal (usually caused by a dead corner and sometimes by the sensor inaccuracy), then $\theta_R \equiv \theta_G$ until the robot switches to the mode of boundary following.

After selecting θ_R, θ_E can be calculated by

$$\theta_E = \underset{\theta \in \Theta}{\arg\min}\left\{\left|\theta - \theta_R\right|\right\}$$
$$\Theta = \left\{\theta \mid \left|\theta - \theta_G\right| < 90^\circ \wedge \theta \in \Theta_S\right\} \tag{4}$$

where Θ_S is the current set of the directions that the robot can keep a safe distance D from obstacles. Note that if $\theta_R = \theta_G$, (4) is degraded to the criterion in the original algorithm [5]. In another word, $\theta_R \equiv \theta_G$ in the original algorithm, but there are more candidates in the improved algorithm and the one that may generate the optimal path according to the heuristic information will be selected.

If $\Theta = \varnothing$, which implies that there is no direction that can both shorten the goal distance and maintain safe for collision avoidance, the robot will switch to Mode 2 after selecting a boundary following direction dir. Such a position is termed a hit-point and each hit-point and the selected dir will be recorded in a list termed Hit-list.

3.2 Boundary Following

Mode 2 is the same as the original algorithm. The concept of finding shortcuts as VisBug and TangentBug are not adopted since it is difficult to always correctly recognize the points in the followed boundary from the range data (we have tried many methods) and it may cause navigation failure. In Mode 2, the robot will record the minimal goal distance d_{Min} and resume Mode 1 once

$$\begin{cases} 0^\circ < \theta_G < 180^\circ \wedge d < d_{\mathrm{Min}} & \text{if } dir = \mathrm{R} \\ -180^\circ < \theta_G < 0^\circ \wedge d < d_{\mathrm{Min}} & \text{if } dir = \mathrm{L} \end{cases} \tag{5}$$

where "L" and "R" represent "left" and "right" to the obstacle, d is the current goal distance. Such a position is termed a leave-point. Additionally, the boundary following direction will be reversed if a previous hit-point (not the current hit-point, i.e., the start point of the current boundary following motion) is met with the same dir as the record in Hit-list (this record is concurrently deleted). Furthermore, if the above event has not occurred after the last time that the robot passed the current hit-point but the current hit-point is met again, the robot can stop and report that the goal is unreachable [5].

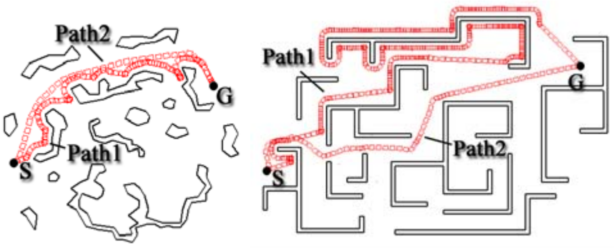
3.3 Convergence Analysis

The improved algorithm can be proved to be convergent. A proof sketch is presented below (the detail is omitted due to the limited space).

It can be proved that there are only finite mode switches and the robot can always switch to Mode 1 from Mode 2 if the goal is reachable [5]. Hence the final mode is Mode 1 if the goal is reachable. According to (4), the goal distance always decreases in Mode 1 even if there are misjudgments for selecting θ_R since $|\theta_E - \theta_G| < 90^\circ$. Therefore, the robot can always reach the goal in Mode 1 as long as it is reachable. Otherwise, it will stop and report that the goal is unreachable in Mode 2.

4 EXPERIMENTAL RESULTS

Based on the MobileSim simulation platform and a model of Pioneer3-AT robot, the improved algorithm has been tested in two environments shown in Fig. 5 with 100 randomly selected start/goal points. The two motion modes are realized by the same control strategy proposed in [5]. In all the simulations, the robot has reached the goal, which verifies the convergence of the improved algorithm. For comparison, the original algorithm has also been simulated in the same conditions. As shown in Table 1, the average path length (APL, which is presented as the relative value to the globally shortest path) generated by the improved algorithm is shorter than the original algorithm in both the environments. The reason is that compared with the original algorithm, the improved algorithm can often shorten the path by bypassing the obstacles in advance with the help of the heuristic information abstracted from the range data.



(a) (b)

Fig. 5. Two simulation results (S is the start point; G is the goal; Path1, Path2 are the paths generated by the original and improved algorithm): (a) environments containing scattered obstacles; (b) a maze environment.

TABLE 1 AVERAGE PATH LENGTH (APL) OF THE SIMULATIONS

Environment	Original Algorithm	Improved Algorithm
Scattered Obstacles	1.983	1.409
Maze	2.233	2.108

The improved algorithm has also been implemented on a real Pioneer3-AT robot. An experimental result is presented in Fig. 6: the robot successfully bypasses the obstacles in advance and finally reaches the goal.

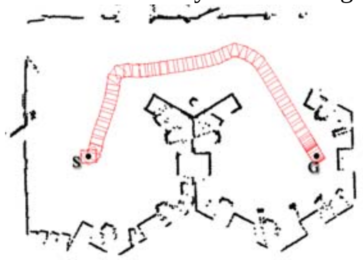


Fig. 6. An experiment on a real robot in an office environment.

5 CONCLUSION

An improved Bug-type algorithm that ensures convergence is proposed in this paper for robot navigation. It improves our previous work [5] by integrating more heuristic information abstracted from the range data to guide the robot. Compared with the similar concepts proposed in VisBug and TangentBug, the improved algorithm is more practical since it has fully considered many implementation issues that are ignored in the these works. Simulations show that it can generate shorter APL than the original algorithm. Experiments on a real robot have further verified its practicability.

Abstract: In this study, we investigate a position search algorithm inspired by the behavior of a water strider, and we develop a six-legged robot that moves toward a sound source autonomously by using this algorithm. First, we observe the behavior of water striders by using a high-speed camera, and we simplify the observed behavior to obtain some rules. Then, we evaluate the validity and effectiveness of the obtained rules by conducting simulations. Finally, we develop a six-legged robot that is controlled on the basis of the obtained rules. Experimental results show that the developed robot effectively moves toward the sound source.

Keywords: water strider, multi-legged robot, acoustic source localization.

1 Introduction

Recently, robots inspired by living beings such as animals and insects have attracted considerable attention. Living beings are able to adapt to complex real-world scenarios in spite of exhibiting simple behavior because they utilize the properties of their environment; in other words, they realize intelligent behavior by interacting with their environment. Thus, by extending the behavior of living beings to robots, we can control robots effectively using simple algorithms.

In this study, we investigate the behavior of a water strider. A water strider moves toward its prey by sensing ripples produced when its prey falls on the surface of a pond. We observe the behavior of a water strider by using a high-speed camera, and we simplify the observed behavior to obtain some rules for moving toward the prey. Then, we evaluate the validity and effectiveness of the obtained rules by conducting simulations. Finally, we develop a six-legged robot that moves toward a sound source on the basis of the obtained rules, and we demonstrate its effectiveness experimentally.

2 Water strider

We observed the behavior of a water strider by using a high-speed camera. Fig. 1 shows how a water strider moves toward its prey, and Table 1 summarizes the behavior of each leg. Fig. 2 shows the leg numbers.

We found that when a ripple is sensed by one of the water strider's legs, it turns in the direction of that leg, and after turning, it moves forward along a straight line. The turning angle is dependent on the leg by which the ripple is sensed first. The water strider repeats this action until it reaches its prey, as shown in Fig 3.

average	2.2	average	40.5	average	120.0

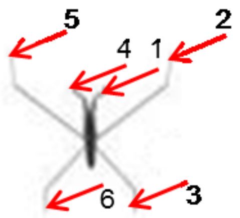

Fig. 2 Leg number

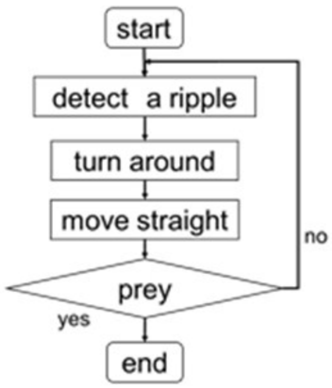

Fig 3. Strategy of water strider

3 Model of water strider

We modeled the water strider by using the following simple rules.

When a leg senses a ripple, the water strider turns in the direction of that leg (The turning angles are listed in Table 2).

Then, it moves forward along a straight line within a certain time period.

This cycle is repeated until the prey is reached.

Table 2. Turning angle

	Leg 1	Leg 2	Leg 3	Leg 4	Leg 5	Leg 6
Turning angle [deg]	2	40	120	-2	-40	-120

Using these rules, the motion of a water strider in time t on a horizontal (xy) plane can be expressed as follows.

$$\theta(t+1)=\theta(t)+\Delta\theta(t) \quad (1)$$

$$x(t+1)=x(t)+v\cos\theta(t) \quad (2)$$

$$y(t+1)=y(t)+v\sin\theta(t) \quad (3)$$

In the equations stated above, x and y denote the position of the water strider, θ denotes its orientation, v denotes its speed (assumed constant), and $\Delta\theta$ denotes its turning angle.

4 Simulation

To evaluate the validity of the simplified model, we conducted simulations. Table 3 lists the simulation parameters, and Fig. 4 shows the simulation results.

Table 3. Simulation parameters

length of water strider [cm]	6
width of water strider [cm]	4.8
speed of water strider [cm/s]	2
interval between ripples [s]	1
speed of ripple [cm/s]	2.5

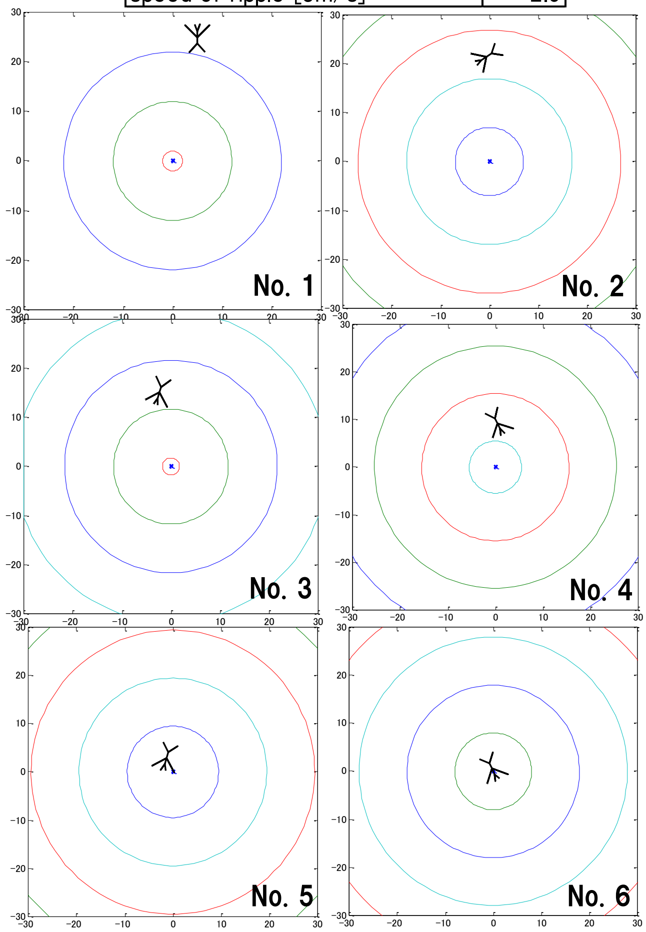

Fig. 4. Simulation results

The results show that the water strider can move toward the ripple source by following the simplified rules.

5 Application to six-legged robot

We developed a six-legged robot, and we adopted the simplified rules to control it.

5.1 Task

Fig. 5 shows the outline of the task. The objective of the task is to move toward the sound source. The position of the sound source is unknown, and the robot moves toward the sound source by using the rules of the water strider.

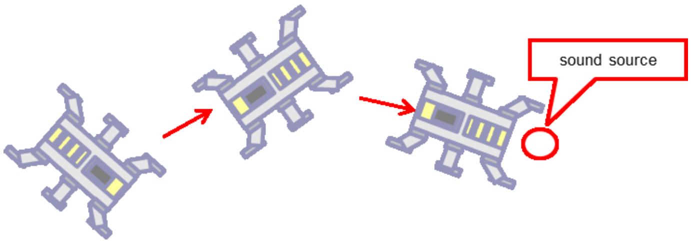

Fig. 5 Task

5.2 Six-legged robot

Fig. 6 shows the developed six-legged robot, and Table 4 lists its specifications. Each leg has two servo motors (Fig. 6 (a)), and it can move from right to left or up and down, as shown in Fig. 7. A microcomputer for controlling the legs is mounted at the center of the body (Fig. 6 (b)). Six microphones are employed to detect sounds; one microphone is attached to each leg (Fig. 6 (c)).

Sound waves from the sound source are detected by the 6 microphones, and the time lag is determined by an electrical circuit (Fig. 6 (d)).

7 CONCLUSION

In this paper, we investigated the behavior of water striders; we observed their behavior by using a high-speed camera in order to obtain simple rules for determining the prey's position. We evaluated the validity and effectiveness of the obtained rules by conducting simulations, and we adopted the rules to control a six-legged robot. Experiments were conducted using the developed robot, and we confirmed that the robot could move toward the sound source. We can conclude that the rules inspired by the water strider are effective in determining the position of the sound source, even though they are very simple.

In the future, we plan to apply these simple rules to useful practical applications such as search and rescue missions for locating survivors in the event of extensive disasters.

Stability of Two-Wheeled Mobile Robot Using New Combined Pole-placement Method

Yoko Amano[1]

[1] Nihon University, Koriyama, Fukushima, 963-8642, Japan
(Tel: 81-24-956-8796, Fax: 81-24-956-8796)

Abstract: In order to guarantee robotic stability, a new combined pole-placement method is proposed in this paper. The proposed method combines the linear quadratic regulator (LQR) into the pole-placement design. Firstly, a mathematical model of Two-Wheeled Mobile Robot (TWMR) is analytically derived from real TWMR. Secondly, the LQR for TWMR model is designed, and optimal poles can be obtained from the designed LQR. Thirdly, selection conditions of the best poles are the following; 1) the guarantee of convergence speed for TWMR system, 2) the number of vibration times for TWMR, 3) saturation evasion of the control input to TWMR's actuators, 4) the ratio of an imaginary part and a real part is carried out near one of selected poles. The pole-placement method selects the best poles than the optimal poles of LQR. Finally, the stability of the proposed method is confirmed by experiment results.

Keywords: inverted pendulum, linear quadratic regulator, pole placement method, two-wheeled mobile robot

1 INTRODUCTION

Two-wheeled mobile robot (TWMR) always exhibits many problems existing in industrial applications, for example, various nonlinear behaviors under different operation conditions, external disturbances, and physical constraints on some variables. Therefore, the task of on-line control of a highly nonlinear unstable has been a challenge for the modern control field. Since the system behaviors of TWMR including actuator dynamics are highly nonlinear, it is difficult to design a suitable control system that realizes real-time control and accurate balancing control at all time.

On the other hand, many research results of TWMR have been applied to various actual problems for designing walking gaits of humanoid robot, robotic wheelchairs, personal transport systems, and so on. Recently, the control problems of TWMR have been intensively studied due to the challenging demand of fast and precise performance. Besides protecting safety of human and robotic operators, the robotic stability is very important research theme at the longest. There have been many studies on the stable problem, for example, sliding-model control [1], fuzzy switched swing-up control [2], and adaptive control [3] are researched on TWMR. But, these controls are very complex and the response time of the mobile robot system is slower.

DC motor torque constant	K_t=0.317	(Nm/A)
Gear ratio	n=1	
Friction coef. of body and DC motor	f_m=0.0022	
Friction coef. between wheel and floor	f_w=0	

using the DC motor voltages v_l and v_r.

$$\begin{aligned} F_\theta &= \left[(2m+M)R^2+2J_m+2n^2J_m\right]\ddot{\theta} \\ &\quad +(MLR-2n^2J_m)\ddot{\psi} \qquad (1) \\ F_\psi &= (MLR-2n^2J_m)\ddot{\theta} \\ &\quad +(ML^2+J_\psi+2n^2J_m)\ddot{\psi}-MgL\psi \qquad (2) \\ F_\phi &= \left[\frac{1}{2}mW^2+\frac{W^2}{2R^2}(J_w+n^2J_m)\right]\ddot{\phi} \qquad (3) \end{aligned}$$

here, consider the limit $\Psi \longrightarrow 0$, and neglect the second order term like $\dot{\Psi}^2$.

2.1 State space model

Now, from (1) to (3), we can obtain the following state space model of TWMR.

$$\begin{aligned} \dot{\boldsymbol{x_1}}(t) &= \boldsymbol{A_1}\boldsymbol{x_1}(t)+\boldsymbol{B_1}\boldsymbol{u}(t) \qquad (4) \\ \boldsymbol{y_1}(t) &= \boldsymbol{C_1}\boldsymbol{x_1}(t) \qquad (5) \end{aligned}$$

where, the state variable $\boldsymbol{x_1}(t)$=$[\theta,\psi,\dot{\theta},\dot{\psi}]^T$, the input $\boldsymbol{u}(t)$=$[v_r,v_l]^T$, and the output $\boldsymbol{y_1(t)}$=$[\theta,\psi,\dot{\theta},\dot{\psi}]^T$, the parameter matrices of the state space model (4), (5) describe the following.

$$\boldsymbol{A_1} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & A_1(3,2) & A_1(3,3) & A_1(3,4) \\ 0 & A_1(4,2) & A_1(4,3) & A_1(4,4) \end{bmatrix} \qquad (6)$$

$$\boldsymbol{B_1} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ B_1(3,1) & B_1(3,2) \\ B_1(4,1) & B_1(4,2) \end{bmatrix} \qquad (7)$$

$$\boldsymbol{C_1} = \text{diag}\ [1 \quad 1 \quad 1 \quad 1] \qquad (8)$$

$$\boldsymbol{E} = \begin{bmatrix} E(1,1) & E(1,2) \\ E(2,1) & E(2,2) \end{bmatrix} \qquad (9)$$

$$\begin{aligned} A_1(3,2) &= -\frac{gMLE(1,2)}{\det \boldsymbol{E}} \\ A_1(4,3) &= \frac{gMLE(1,1)}{\det \boldsymbol{E}} \\ A_1(3,3) &= -\frac{2\left[(\beta+f_w)E(2,2)+\beta E(1,2)\right]}{\det \boldsymbol{E}} \\ A_1(3,4) &= \frac{2\left[(\beta+f_w)E(1,2)+\beta E(1,1)\right]}{\det \boldsymbol{E}} \\ A_1(4,3) &= \frac{2\beta\left[E(2,2)+E(1,2)\right]}{\det \boldsymbol{E}} \\ A_1(4,4) &= -\frac{2\beta\left[E(1,1)+E(1,2)\right]}{\det \boldsymbol{E}} \\ B_1(3,1) &= \frac{\alpha\left[E(2,2)+E(1,2)\right]}{\det \boldsymbol{E}} \\ B_1(4,1) &= -\frac{\alpha\left[E(1,1)+E(1,2)\right]}{\det \boldsymbol{E}} \\ \det(\boldsymbol{E}) &= E(1,1)E(2,2)-E(1.2)^2 \end{aligned}$$

$$\begin{aligned} E(1,1) &= (2m+M)R^2+2J_w+2n^2J_m \\ E(1,2) &= MLR-2n^2J_m \\ E(2,1) &= MLR-2n^2J_m \\ E(2,2) &= ML^2+J_\psi+2n^2J_m \end{aligned}$$

$$\alpha=\frac{nK_t}{R_m}, \qquad \beta=\frac{nK_tK_b}{R_m}+f_m$$

2.2 LQR design for TWMR

In this section, LQR design for TWMR is considered as an expansive state space equation. We select θ as a reference state $\boldsymbol{\theta_{ref}}$=$\boldsymbol{C_\theta}\boldsymbol{x}_{1ref}$, and define an error $\boldsymbol{e}(t)$=$\mathrm{C}_\theta\boldsymbol{x}_{1ref}$-$\theta(t)$, $\dot{z}(t)=\mathrm{e}(t)$, then the expansive state space equation can be expressed by

$$\dot{\bar{\boldsymbol{x}}}(t)=\bar{\boldsymbol{A}}\bar{\boldsymbol{x}}(t)+\bar{\boldsymbol{B}}\bar{\boldsymbol{u}}(t) \qquad (10)$$

$$\dot{\bar{\boldsymbol{x}}}(t)=\begin{bmatrix} \dot{\boldsymbol{x}}(t) \\ \dot{\boldsymbol{z}}(t) \end{bmatrix}, \bar{\boldsymbol{A}}=\begin{bmatrix} \boldsymbol{A_1} & 0 \\ 0 & \mathrm{C}_\theta \end{bmatrix},$$

$$\bar{\boldsymbol{B}}=\begin{bmatrix} \boldsymbol{B_1} & 0 \\ 0 & \text{-}\mathrm{C}_\theta \end{bmatrix}, \bar{\boldsymbol{u}}(t)=\begin{bmatrix} \boldsymbol{u}(t) \\ \boldsymbol{x_1}(t) \end{bmatrix}$$

According to an optimal feedback gain matrix $\boldsymbol{K}$ such that the feedback control law

$$\begin{aligned} \bar{\boldsymbol{u}}^*(t) &= -\boldsymbol{K}\bar{\boldsymbol{x}}(t) \qquad (11) \\ &= \begin{bmatrix} -\boldsymbol{k_f} & -\boldsymbol{k_i} \end{bmatrix}\begin{bmatrix} \boldsymbol{x}(t) \\ \boldsymbol{z}(t) \end{bmatrix} \qquad (12) \\ \boldsymbol{K} &= \boldsymbol{R}^{-1}\bar{\boldsymbol{B}}^T\boldsymbol{P} \qquad (13) \end{aligned}$$

minimizes the performance index

$$J = \int_0^\infty (\bar{\boldsymbol{x}}^T(t)\boldsymbol{Q}\bar{\boldsymbol{x}}(t)+\bar{\boldsymbol{u}}^T(t)\boldsymbol{R}\bar{\boldsymbol{u}}(t))dt \qquad (14)$$

subject to the constaint equation (10). Here, matrix $\boldsymbol{P}$ of (13) is the unique positive-definite solution of the associated matrix Riccati Equation

$$\bar{\boldsymbol{A}}^T\boldsymbol{P}+\boldsymbol{P}\bar{\boldsymbol{A}}+\boldsymbol{Q}-\boldsymbol{P}\bar{\boldsymbol{B}}\boldsymbol{R}^{-1}\bar{\boldsymbol{B}}^T\boldsymbol{P}=0 \qquad (15)$$

As stated above, a servo control for TWMR is shown in Fig.2, where $\boldsymbol{C_\theta}$ = diag $[1, \quad 0, \quad 0, \quad 0]$, and the weight matrices $\boldsymbol{Q}$, $\boldsymbol{R}$ of (13) by experimental trial and error.

$$\begin{aligned} \boldsymbol{Q} &= \text{diag}\ [1 \quad 6\times10^5 \quad 1 \quad 1 \quad 4\times10^2] \qquad (16) \\ \boldsymbol{R} &= \text{diag}\ [1\times10^3 \quad 1\times10^3] \qquad (17) \end{aligned}$$

To calculate the LQR problem, and obtain the gain $\boldsymbol{K}$ is

$$\begin{aligned} \boldsymbol{K} &= [k_\theta,\ k_\psi,\ k_{\dot{\theta}},\ k_{\dot{\psi}},\ k_i] \qquad (18) \\ \boldsymbol{K} &= [-0.867,\ -31.931,\ -1.154,\ -2.783,\ -0.446] \end{aligned}$$

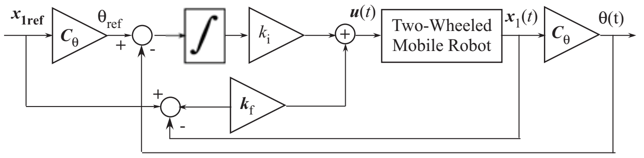

Fig. 2 Servo control system block diagram

3 PROPOSED METHOD

In this section, we present a design proposed method called a combined pole-placement method. We assume that all state variables are measurable and are available for feedback. If the system considered is completely state controllable, then poles of the closed-loop system may be placed at any desired locations by means of state feedback through an appropriate state feedback again matrix.

The present design technique begins with a determination of the desired closed-loop poles based on the transient-response and frequency-response requirements, such as speed, damping ratio, and bandwidth, sa well as steady-state requirements.

3.1 Pole-placement for TWMR

From the expansive state space equation (10) and the optimal control input (11), the closed-loop system can be expressed as

$$\begin{aligned}\dot{\bar{\boldsymbol{x}}}(t) &= \bar{\boldsymbol{A}}\bar{\boldsymbol{x}}(t) - \bar{\boldsymbol{B}}\boldsymbol{K}\bar{\boldsymbol{x}}(t) \\ &= (\bar{\boldsymbol{A}} - \bar{\boldsymbol{B}}\boldsymbol{K})\bar{\boldsymbol{x}}(t) \qquad (19)\end{aligned}$$

The desired characteristic equation is

$$\begin{aligned}|s\boldsymbol{I} - \bar{\boldsymbol{A}} + \bar{\boldsymbol{B}}\boldsymbol{K}| &= (s-p_1)(s-p_2)\cdots(s-p_n) \\ &= s^n + a_{n-1}s^{n-1} + \cdots + a_0 = 0 \qquad (20)\end{aligned}$$

where, p_i (i=1, 2, $\cdots$, n) are poles of the closed-loop system (19). The first step in the pole-placement design approach is to choose the locations of the desired closed-loop poles. The most frequently used approach is to choose such poles on basis of experience in root-locus design, placing a dominant pair of closed-loop poles and choosing other poles so that are far to the left of the dominant closed-loop poles.

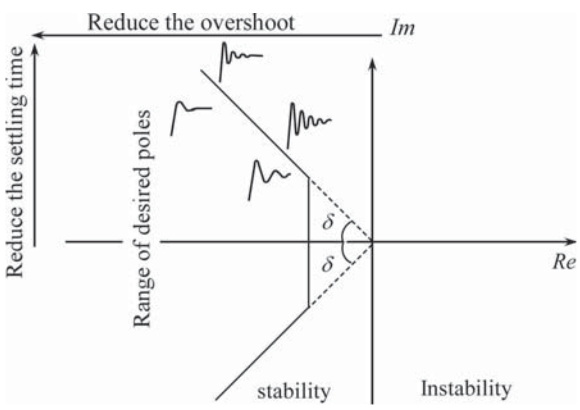

Fig.3 Range of desired poles

We have to note that if the dominant closed-loop poles is far from the $j\omega$-axis, so that the system response becomes very fast, the signals in the system become very large, with the result that system may become nonlinear, this should be avoided and shown in Fig.3.

Another approach is based on LQR approach and determines the desired closed-loop poles such that the system balances between the acceptable response and the amount of control energy required.

In the complex coordinate of Fig.3, an angle $\delta = tan^{-1}(\sqrt{1-\zeta^2}/\zeta)$, here ζ is a damping ratio. For servo control system of robotics, TWMR and so on, $\zeta = 0.6 - 0.8$ and $\delta = 37° - 53°$ have been generally accepted [5].

3.2 Choosing the location of desired closed-loop poles

From $\boldsymbol{K}$ of (18), the pole $\boldsymbol{P_0}$ can be derived and shows the following

$$\boldsymbol{P_0} = [-284.41, -10.92, -1.3 \pm j0.73, -1.47] \qquad (21)$$

We change the damping ratio ζ with 0.05 step from 0.6 to 0.8, and obtain poles $\boldsymbol{P_i}$ $(i = 1, \cdots, 5)$ their feedback gains, the ζ and the natural frequency ω_n are shown in Table 2, 3 and 4, respectively.

Table 2 Closed-loop poles

	p_1	p_2	p_3, p_4	p_5
$\boldsymbol{P_0}$	-284.41	-10.9	$-1.3 \pm j0.73$	-1.47
$\boldsymbol{P_1}$	-284.41	-10.9	$-1.3 \pm j0.96$	-1.47
$\boldsymbol{P_2}$	-284.41	-10.9	$-1.3 \pm j1.15$	-1.47
$\boldsymbol{P_3}$	-284.41	-10.9	$-1.3 \pm j1.31$	-1.47
$\boldsymbol{P_4}$	-284.41	-10.9	$-1.3 \pm j1.51$	-1.47
$\boldsymbol{P_5}$	-284.41	-10.9	$-1.3 \pm j1.73$	-1.47

Table 3 Feedback gains

	k_θ	k_ψ	$k_{\dot{\theta}}$	$k_{\dot{\psi}}$	k_i
$\boldsymbol{P_0}$	-0.867	-31.931	-1.154	-2.783	-0.446
$\boldsymbol{P_1}$	-0.927	-32.059	-1.160	-2.797	-0.524
$\boldsymbol{P_2}$	-0.990	-32.191	-1.167	-2.810	-0.604
$\boldsymbol{P_3}$	-1.051	-32.320	-1.173	-2.823	-0.683
$\boldsymbol{P_4}$	-1.138	-32.506	-1.182	-2.841	-0.796
$\boldsymbol{P_5}$	-1.249	-32.741	-1.193	-2.865	-0.939

Table 4 Damping ratio and Natural frequency

	Damping ratio ζ	Natural frequency ω_n (rad/s)
$\boldsymbol{P_0}$	0.87	1.49
$\boldsymbol{P_1}$	0.80	1.62
$\boldsymbol{P_2}$	0.75	1.74
$\boldsymbol{P_3}$	0.70	1.85
$\boldsymbol{P_4}$	0.65	1.99
$\boldsymbol{P_5}$	0.60	2.16

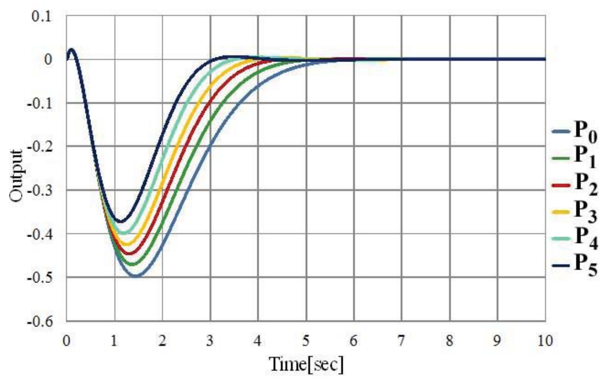

Fig.4 Unit step responses with $\boldsymbol{P_i}$

Figure 4 shows unit step responses of the closed-loop with $\boldsymbol{P_i}$. On the same method, we keep the ζ, and change the real number of the conjugate number $-1.3 \pm j0.73$ with 0.2 step to negative direction. We obtain the good pole $\boldsymbol{P_6} = [-284.4,\ -10.9,\ -1.5 \pm j0.84,\ -1.47]$ with gain margin 5.0 [dB], resonant peak -10.1 [dB], setting time 4.79 (sec.), overshoot -0.41, and $\zeta = 0.87$, $\omega_n = 1.72$ (rad/sec.).

4 EXPERIMENTAL RESULTS

A real TWMR is established practically in our laboratory to illustrate the effectiveness of the proposed method. Using the same parameters shown in Table 1, real stable position experiment is implemented to verify the feasibility of the proposed method with the pole $\boldsymbol{P_6}$ and the LQR method with $\boldsymbol{P_0}$, respectively.

Fig.5 presents the body angle Ψ which tests the stability of TWMR, a small shaking of the body angle with the pole $\boldsymbol{P_6}$ than the pole $\boldsymbol{P_0}$. Fig.6 shows the shifting distance of TWMR at an appointed position. A large distance error using the pole $\boldsymbol{P_0}$ is produced, but, the proposed method with the pole $\boldsymbol{P_6}$ generates very small movement from the appointed position.

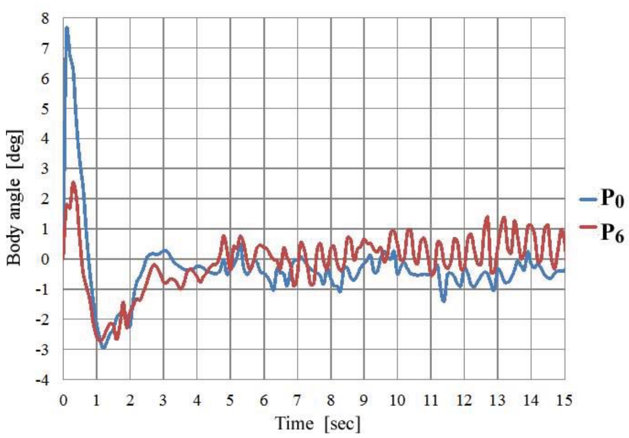

Fig.5 Experimental results of body angle

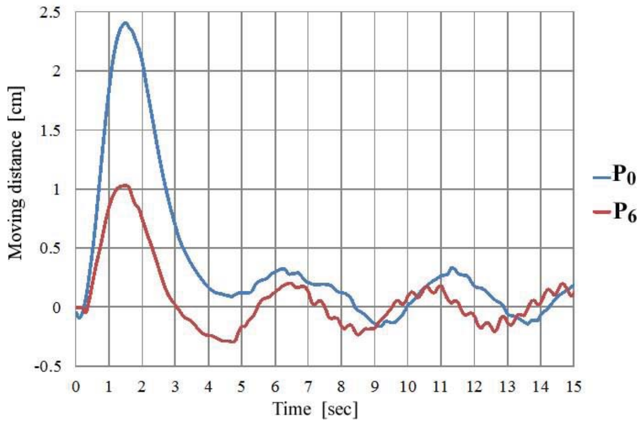

Fig.6 Experimental results of shifting distance

5 CONCLUSION

This paper has implemented the LQR method and pole-placement developmental hardware and software on the real TWMR system, the combined pole-placement method has been newly proposed to control TWMR achieving the desired control behaviors than LQR method.

Finally, the experiment of stable position control was executed using the proposed method and LQR method, the experimental results indeed have verified that the proposed method is effective for the real TWMR system.

Abstract: The internet has significantly changed most people's environments. It is possible to search for and obtain information about nearly any subject, and it is possible to purchase many things on the internet. Music files can be purchased, and lyrics can be searched via web services, which is convenient for consumers. However, even if the singer, a part of the musical phrase and the release date are known, a song cannot be accessed if one does not remember the name of the song. If one could enter a sample of the voice, do a search using that voice's length and pitch, find the rhythm and a similarly pitched phrase, it may be possible to determine the name of the song. Therefore, we developed a phrase and music search engine. It searches for a tune from among various tunes, using one phrase of voice data. For the purpose of studying the relationship between tempo and pitch changes related to the frequency of the input voice data, we developed a method using dynamic programming (DP) matching as a way to search for similar phrases. This system converts notes into character strings, runs DP matching using the strings, and calculates the degree of disagreement between these strings. We then use these calculations as an index to determine whether the strings resemble each other.

***Keywords*:** automatic piano, knowledge database, computer music, DP matching

I. INTRODUCTION

The internet has significantly changed most people's environments. It is possible to search for and obtain information about nearly any subject, and it is possible to purchase many things on the internet.

Music purchases are no exception. Previously, CDs were purchased or rented from stores, but now they can be purchased or rented from home. This is convenient for consumers. However, even if the singer, a part of the musical phrase and the release date are known, a song cannot be accessed if one does not remember the name of the song.

On the other hand, related to music performance, we have developed pedal-powered equipment and typing equipment. The problem of fast repetitive typing with the same key and complaints about performance have been solved, and a system in which piano playing takes place automatically has been developed. That system can make use of data when you play piano with MIDI functions and edited data of loudness, the length of the sound, tempo, etc [1]. In addition, studies were conducted two years ago at time of the development of an interactive musical editing system. That system made it possible to perform efficient editing of large music data files. The automatic piano performs the music of the large musical data files. Finding the desired song requires a time-consuming search for the correct musical data. So, we thought it would be useful to have a music information search engine. The system makes an efficient search for the desired song names and musical data, which can reduce the burden on the user.

In this research we developed a system that uses DP matching to search the entire score to look for a match to a given phrase. This system converts notes into character strings and calculates the degree of disagreement between these strings during searching. We use these calculations as an index to determine whether the strings resemble each other.

In this paper, we describe the results of searching for similar phrases using DP matching.

Figure 1.1: View of the automatic piano

II. Musical Editing Support System

2.1 System Architecture

The structure of the system is shown in Figure 2.1. The user edits music via the user's interface on a

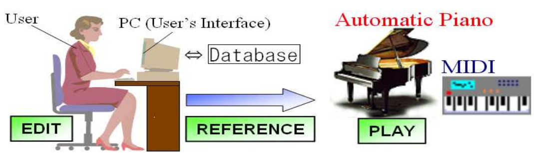

Figure 2.1: Structure of the editing system

computer display. The user can also access a database that has musical grammar, the user's preferences, and so on. As a result, editorial work is reduced and efficient editing becomes possible.

2.2 Performance information

The score is read by the scanner. Scanned data is converted to MusicXML format by the KAWAI Score Maker FX5 program. A database of performance information containing notes, scales, and symbols of music data is created based on the MusicXML data. The created database will be subject to search.

2.2.1 Format of Performance Information

The parameters of performance information are shown in Tables 1 and 2. The automatic piano that we have developed uses a music data structure that is similar to MIDI. We defined performance information, dividing it into two categories: the notes and the pedals. The note information is comprised of the six parameters involved in producing a tone: "Key" (note), "Velo" (velocity), "Gate", "Step", "Bar", and "Time". "Velo" is the dynamics, given by the value of 1–127. "Gate" is the duration of the note in milliseconds. "Step" is the interval of time between notes, and it also exhibits tempo. "Bar" is the vertical line placed on the staff to divide the music into measures.
The pedal information is comprised of four parameters: "Key" (indicating the kind of pedal: "Damper" or "Shifting"), "Velo" (the pedaling quantity), "Time" (the duration for which the pedal is applied)", and "Bar".

Table 2.1: Format of the note information

Parameters	Unit (numerical value)	Resolution	Setting
Key	21~108	Stage 88	Pitch
Velo	1~127	Stage 127	Volume
Gate	ms	1ms	Length
Step	ms	1ms	Interval
Time	ms	1ms	Pronunciation time
Bar	-	-	Bar numbers

Table 2.2: Format of the pedal information

Parameters	Unit (numerical value)	Resolution	Setting
Key	119 or 110	-	119=Damper,110=Shift
Velo	0~127	Stage 128	Position of the pedal
Time	ms	1ms	Pedal operation start time
Bar	-	-	Bar numbers

III. Phrase and music search engine

3.1 System summary

We developed a phrase and music search engine. It searches for one tune from among various tunes using one phrase of voice data. The voice is first inputted; then the interval between the sounds of the inputted voice data is converted back to notes according to the tempo of the music. The system then searches for sequence similarity to the phrase rhythm and notes.

In addition, the pitch of the voice input data was analyzed and pitch changes were calculated. Pitch changes are indicated by the ratio of the pitch of a sound to the pitch of the previous one. By using the change in pitch, we hoped to improve the retrieval accuracy of our system.

3.3 Processing that inputs voice

Voice is input in the shape of waves, as shown in Figure 3.1. The vertical axis of Figure 3.1 shows loudness, and the horizontal axis shows time. By setting a threshold on the vertical axis, the presence of voice can be recognized. The interval of this sound is measured as the time. In other words, as shown in Figure 3.1, the interval of sound is the period between the initial iterative peak and the next sound iterative peak.

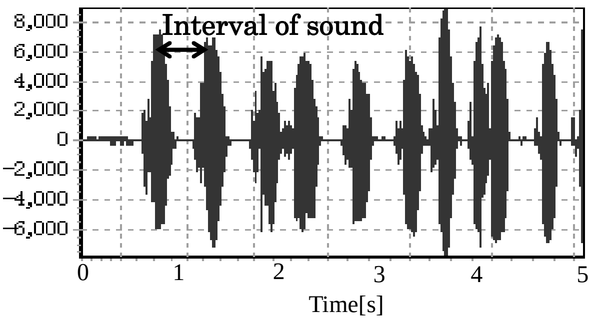

Figure 3.1: Result of sound input

3.4 Converting notes

Measurements of the interval of sound are converted to notes based on the velocity symbol, which appears at the top of the score and represents the number of beats per minute. For example, the indication in Figure 3.2 means 120 quarter note beats per minute. In other words, the length of a quarter note would be 0.5 seconds. The interval of sound is converted into note by using the length of a quarter note.

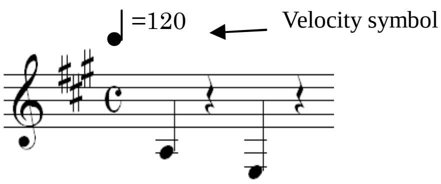

Figure 3.2: Velocity symbol of score

3.5 Frequency analysis of voice data

Pitch is determined by the frequency of the sound, and pitch changes can be determined by the transition of frequency. The voice data frequency analysis is performed using the FFT (fast Fourier transform) algorithm.

Frequency analysis of the voice waveform is conducted for each fixed intervals. And, in one interval, the highest power spectrum frequency is recorded as the main frequency.

IV. Searching for Similar Phrases

As a result of the analysis, it was found that phrases of the same pattern existing in the same tune are performed in a similar expression. In the present study, we used DP matching to search for similar phrases.

4.1 DP matching

DP matching is a technique used widely in the field of speech recognition, bioinformatics and so on. It can calculate the similarity between two words that are different from each other in a number of characters.

In Figure 4.1, the route of minimum cost in each point is taken, and the route with the lowest cost is assumed finally to be the optimal path. The cost at that time is defined as the distance between patterns. In this system, this distance is handled as a threshold to judge whether the phrases are similar to each other.

For example, if the cost moves up or to the right, then it is increased by 1. If it moves to the uppermost level on the right, then it does not increase. Also, if the characters do not correspond in each point, then the cost is increased by 5.

$$g(i,j) = \min\left\{\begin{matrix} g(i-1,j) \\ g(i,j) \\ g(i,j-1) \end{matrix}\right\} + d(i,j)$$

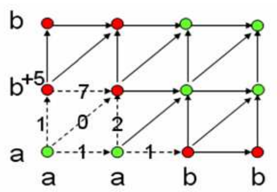

Figure 4.1: DP matching

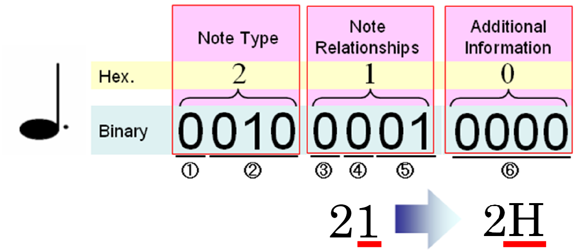
4.2 Searching with DP matching

In this section we describe a method of searching with DP matching. We had to convert a musical score into character strings (a Note Pattern) before searching for similar phrases. This process is explained below.

4.2.1 Patterning

Each note is expressed by three hexadecimal numbers and patterned using only the digits in the first two decimal places, as shown in Figure 4.2 However, the meanings of these two digits vary. Therefore, to avoid confusion, the second digit is distinguished by applying the letter of the alphabet (V from G).

In addition, the sound frequency obtained in Section 3.5 is made into a pattern. First, the system determines the frequency ratio of two successive sounds, and then the ratio of the frequency is patterned by size, as shown in Figure 4.3



① Note or Rest (0: Note, 1: Rest)
② Note Value (000: A whole note, 001: A half note ...etc)
③ Tie (If the note has a tie then this number is 1.)
④ Ornament
(If the note has an ornament then this number is 1.)
⑤ The number of dots
(Exceptionally, if it is "11" then the note is a tuplet.)
⑥ Additional Information

Figure 4.2: Patterning of notes

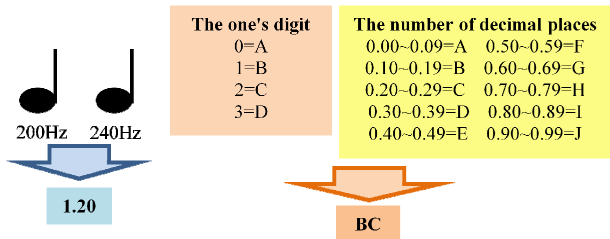


Figure 4.3: Patterning of frequency

4.2.2 The method of searching

A flow chart of a search for a music phrase similar to an input phrase is shown in Figure 4.4.

First, the data of patterned notes column is matched. The phrases with little distance between patterns are searched. Music containing those phrases becomes a search result candidate.

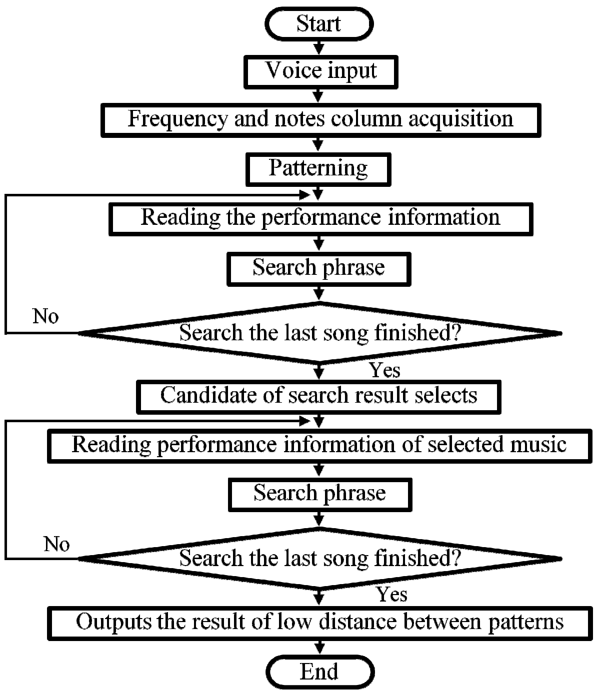

Figure 4.4: The flow of the similar phrase search

Next, the data of patterned sound frequency ratio are matched. Candidates of the search results are narrowed by matching of the frequency ratio.

The search is performed song by song through the database. When the search engine has processed one song, it then proceeds to the next song, continuing to look for the phrase. When the song changes, search engine is change the tempo of the song. And, search phrase is patterned again. After pattern matching in each of two, search result of the lowest distance between patterns is outputted.

V. Retrieval experiment and consideration

We searched for music using the phrase and music search engine. The phrase beginning in bar 59 of "SEKAI NI HITOTU DAKE NO HANA" is sung. The music is searched based on the inputted voice data.

First, the data of the patterned notes column is matched. The system output phrases with a distance of 10 or less. Next, the data of the patterned output phrase frequency ratio is matched. Table 5.1 summarizes the results of the matching. Figure 5.1 represents graphically the difference in the frequency ratio.

A glance at the distance between patterns (Note column) of Table 5.1 will reveal that the phrase beginning in bar 32 of "SEKAI NI HITOTU DAKE NO HANA" and the phrase beginning in bar 59 of the same music are the smallest. However, a search cannot determine the correct one because the two phrases have the same value.

On the other hand, a glance at the distance between patterns (Frequency) of Table 5.1 will reveal that the phrase beginning in bar 32 of "SEKAI" is lower than the phrase beginning in bar 59 of the same music. Thus, in terms of frequency ratios, it is revealed that the phrase begiining in bar 32 is similar to the phrase beginning in bar 59 of "SEKAI NI HITOTU DAKE NO HANA".

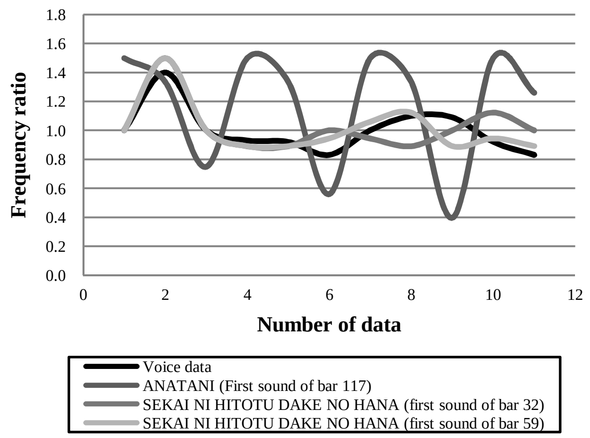

Figure 5.1: Difference in the frequency ratio

Table 5.1: Search result

Name of Music	Bar Number	Note Number	Distance between patterns (Note column)	Distance between patterns (Frequency)
SEKAI NI HITOTU DAKE NO HANA	28	2	10	42
SEKAI NI HITOTU DAKE NO HANA	32	1	5	31
SEKAI NI HITOTU DAKE NO HANA	43	2	10	25
SEKAI NI HITOTU DAKE NO HANA	59	1	5	25
ANATANI	117	1	10	55
ANATANI	118	1	10	55

VI. CONCLUSION

We designed methods of searching for similar phrases using DP matching and combined these functions into a single system.

In the similar phrase search, the system was able to find similar phrases using DP matching in a short time, and it was even possible to find phrases whose resemblance might not be immediately apparent.

In the phrase and music search engine, we developed a system to search for a tune by inputting the data of a voice performing the tune. The interval between the sounds of the inputted voice data is converted to a note according to the tempo of the music. Using this technique, we can search for sequence similarity to a phrase's rhythm and notes. In addition, the search using the patterns of frequency ratio became possible. The search using the patterns of frequency ratio could improve the retrieval accuracy.

In this study, we were able to perform similar phrase searches and searching for a tune by voice. In our future research we will perform evaluations with different pieces of music and will evaluate the existing system.

Abstract: Elementary living beings, like bacteria, are able to reach food sources using only limited and very noisy sensory information. In this paper we describe a very simple algorithm inspired from bacteria chemotaxis. We present a Markov chain model for studying the effect of noise on the the behavior of an agent that moves according to this algorithm, and we show that, counterintuitively, the application of noise can increase the expected average performance over a fixed available time. After this theoretical analysis, experiments on real world application of this algorithm are introduced. In particular, we show that the algorithm is able to control a complex robot arm, actuated by 17 McKibben pneumatic artificial muscles, without the need of any model of the robot or of its environment.

Keywords: Robotics, Control techniques, Artificial life

1 INTRODUCTION

Bacteria chemotaxis, the process by which bacteria move toward increasing concentrations of nutrients, is an important topic of the biological field. In particular, the movement of Escherichia Coli (E. Coli) was intensively studied [1]. This bacterium has only two ways of moving, rotating its flagella in clockwise or counterclockwise direction. When the flagella rotate counter-clockwisely they align into a single bundle and the bacterium swims in a straight line. Conversely clockwise rotations break the flagella apart and the bacterium tumbles in place. The bacterium keeps alternating clockwise and counterclockwise rotations. In absence of chemical gradients, the length of the straight line paths, i.e. the counterclockwise rotations, is independent of the direction.

In case of a positive gradient of nutrients, E. Coli reduces its tumbling frequency. In other terms, when the concentration of nutrients increases the bacterium proceeds in the same direction for a longer time. This simple strategy, usually modeled by a biased random walk, is able to drive bacteria to high concentrations of nutrients despite the difficulties in precisely sensing the gradient.

In [2] we proposed a simplified, more generic model for the movement of E. Coli, that we termed *Minimalistic Behavioral Rule* (MBR). Simulations with this model showed that while in most engineering approaches noise is considered as a nuance, that must be filtered to extract the underlying information, noise can actually help bacteria in reaching high concentrations of nutrients.

This paper provides a theoretical analysis of the phenomenon. A Markov chain model is introduced in section 3 to explain the beneficial effect of noise on the movement of an MBR-driven agent. The possibility of employing MBR for the control of complex systems is then shown experimentally by using a robot arm driven by pneumatic actuators (Section 4). Finally, Section 5 concludes the paper by discussing the results.

2 ALGORITHM

As briefly described in the previous section, E. Coli proceeds in the same direction for longer times when the conditions are improving, i.e. when the the concentration of nutrients increases, and proceeds by random walk otherwise. In [2] we defined a very general control algorithm that follows a similar principle. This algorithm, besides being able to explain phenomena regarding bacteria chemotaxis, can be applied for the control of robots, as will be shown in this paper. More formally, the algorithm can be described in the time-discrete domain as follows. Let us denote by E_t an evaluation function (e.g. the concentration of nutrient in the bacteria's case), and by ΔE_t its variation from time $t-1$ to time t. Let us then define a generic motor command $u_t \in \mathbb{R}^n$ that the agent sends to its actuators. The MBR sets u_{t+1} as

$$u_{t+1} = \begin{cases} u_t + \eta R & if\ \Delta E_t \geq 0 \\ random\ selection & otherwise \end{cases}. \quad (1)$$

where $R \in \mathbb{R}^n$ is a random variable, $\eta \in \mathbb{R}$ is a multiplying factor and "random selection" corresponds to randomly picking a motor command in the whole motor command space. Intuitively, MBR tells to change randomly the motor command when the conditions get worse, and keep the current motor command when conditions are improving. In more detail, when the conditions are improving, the motor command is not kept identical to the previous step, but it is slightly modified, with a random perturbation whose inten-

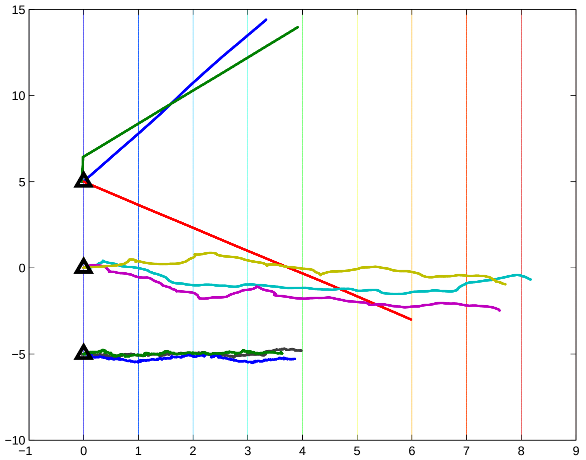

Fig. 1. Paths taken by agents with different values of η: agents starting from $[0,-5]^T$, $[0,0]^T$ and $[0,5]^T$ have, respectively low, medium and high values of η. Each trajectory corresponds to 100 time steps of the agent.

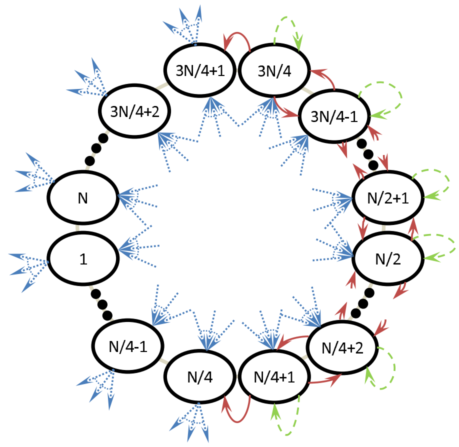

Fig. 2. Representation of the Markov chain. Blue dotted arrows represent the selection of a new node with uniform, $1/N$ probability. Red solid arrows represent transition to the neighboring states with probability v and green dashed arrows indicate loops of probability $1-2v$.

sity is modulated by η. Fig. 1 shows an example of the effect of this random perturbation on the movement of an MBR-controlled agent. Suppose to have an agent that moves on a 2D plane. Let $x \in \mathbb{R}^2$ be the agent position. Assume the agent to move by steps of fixed length s, along the angle indicated by $u_t \in \mathbb{R}$, i.e. $x_{t+1} = x_t + s \cdot [\cos(u_t), sin(u_t)]^T$ and to have an evaluation function that increases along the x axis, i.e. $E_t = [1,0]^T x_t$. If the perturbation η is too small, as for the agents starting from $[0,5]^T$ in Fig. 1, then every motor command u that that bring brings the agent closer to the target, even a very tangential and inefficient one, will be employed for a long time. If the perturbation is too big, as for the agents starting at the bottom of the figure, then the agent keeps changing direction, even when the movement is headed straight to the goal. If the perturbation amplitude η is appropriate, as for the agents starting in the middle of Fig. 1, then the agent will rapidly increase E_t with a good trajectory.

3 THEORETICAL ANALYSIS

In order to understand the reasons of the performance improvement given by an opportune value of $\eta \neq 0$, let us consider again example reported in the previous section. Let us discretize the direction taken by the agent into N possible states of a Markov chain, with the state i, $1 \leq i \leq N$ indicating the probability of taking the directions in the range $\left[-\pi + \frac{2\pi(i-1)}{N}, -\pi + \frac{2\pi+i}{N}\right)$. Let us restrict to the case where transitions due to the perturbation η are limited to neighboring states. In particular, let us assume to transit from a state i to one of its neighbors $i+1$ and $i-1$ with probability v, and remain in the same state with probability $1-2v$, as shown in Fig. 2. We note that only for the states corresponding to directions that lead to an increase of E_t, i.e. the states $\frac{N}{4}+1 \leq i \leq \frac{3N}{4}$, such outward transition to the neighboring states exist. The states corresponding to directions for which $\Delta E_t < 0$, i.e. the directions that imply a random selection in the MBR, have outward transitions that reach each state, including the current state, with probability $1/N$.

The evolution of the probability of the states is described by the following equations. Let us denote by $p_{i,t}$ the probability of being in state i at time t, and by $g = \frac{1-\sum_{i=N/4+1}^{3N/4} p_{i,t}}{N}$ the probability of being selected by random selection when $\Delta E_t < 0$. With these definitions

$$p_{i,t+1} =$$

$$\begin{cases} vp_{i+1,t} + g & if\ i = \frac{N}{4} \\ (1-2v)p_{i,t} + vp_{i+1,t} + g & if\ i = \frac{N}{4}+1 \\ (1-2v)p_{i,t} + v(p_{i+1,t} + p_{i-1,t}) + g & if\ \frac{N}{4}+2 \leq i \leq \frac{3N}{4}-1 \\ (1-2v)p_{i,t} + vp_{i-1,t} + g & if\ i = \frac{3N}{4} \\ vp_{i-1,t} + g & if\ i = \frac{3N}{4}+1 \\ g & otherwise \end{cases} \tag{2}$$

Intuitively, when $v \neq 0$ at every time step there is a "flow of probability" between the nodes. In detail, even starting from a uniform probability of the nodes $p_{i,0} = 1/N$, the nodes $1 \leq i \leq \frac{N}{4}$ and $\frac{3N}{4}+1 \leq i \leq N$ assume a lower probability in one time step. This causes a flow of probability from nodes $\frac{N}{4}+1$ to $\frac{N}{4}$, $\frac{N}{4}+2$ to $\frac{N}{4}+1$, etc. (and, symmetrically, from $\frac{3N}{4}-k$ to $\frac{3N}{4}-k+1$, for $0 \leq k \leq \frac{N}{4}-1$).

Fig. 3 shows the evolution of the probability for different values of v (corresponding, in the MBR, to different values of η) at different time instants t starting from a uniform distribution, i.e. starting from a random direction of the agent. We note that at the beginning a higher value of v is able to "speed up the flow", that makes the distribution peaky around states

$\frac{N}{2}$ and $\frac{N}{2}+1$, corresponding to angles close to 0. As times goes on, however, the distribution becomes more peaky for lower settings of v, as shown in the last panel of Fig. 3.

Let us analyze the chain for $t \to \infty$. The stationary distribution, computed from Eq. 2 and $p_{i,t+1} = p_{i_t}$, is

$$p_{i,t+1} = \begin{cases} \frac{24(n+4)v}{n(8+6n+n^2+96v)} & if i = \frac{N}{4} \wedge i = \frac{3N}{4}+1 \\ \frac{-48i^2+48i(n+1)-12n-9n^2}{n(8+6n+n^2+96v)} & if \frac{N}{4}+1 \leq i \leq \frac{3N}{4} \\ \frac{96v}{n(8+6n+n^2+96v)} & otherwise \end{cases} \tag{3}$$

If we take the derivative with respect to v we find that $\frac{dp_{i,\infty}}{dv}$ is always negative for $\frac{N}{4}+1 \leq i \leq \frac{3N}{4}$ (states that lead to positive ΔE_t) and always positive for the other states (that lead to a negative ΔE_t). In other terms, over short times high values of v are preferable, but as the time available increases, it is more efficient to have a lower value of v. In short, there is a trade-off between the speed with which good

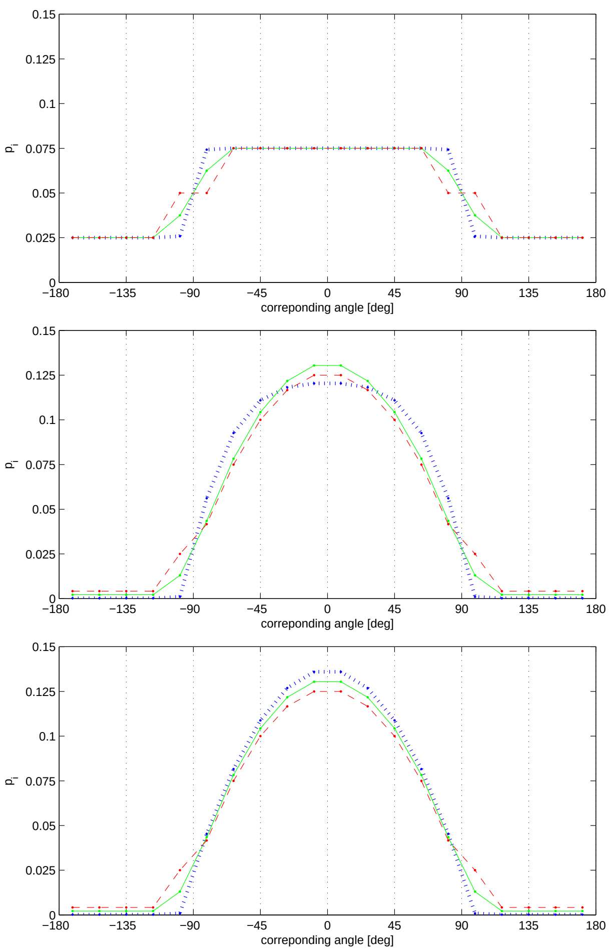

Fig. 3. Probability of a Markov chain of $N = 20$ states starting from a uniform distribution at time $t = 0$. Each panel corresponds to a time instant: $t = 1$ (top panel), $t = 10$ (central panel) and $t = 10^{10}$ (bottom panel). Each panel reports the distribution obtained 3 different values of v: $1/64$ (blue dotted line), $1/4$ (green solid line) and $1/2$ (red dashed line).

motor commands u are chosen, increased by higher values of η, and the precision obtained after a long period, improved by decreasing η. Section 5 will briefly discuss this issue.

These relationships between the noise intensity η, the distribution of the directions taken by the agent and time can be confirmed by numerical simulations of the MBR, with results that resemble the Markov chain approximation here introduced. Actually, the probability density function $p(\theta)$ of taking direction θ is the solution of the following Fredholm integral equation of the second type:

$$\begin{aligned} p(\theta) &= \int_{-\pi/2}^{\pi/2} K(\theta,\phi)p(\phi)d\phi + \frac{1-\int_{-\pi/2}^{\pi/2} p(\phi)d\phi}{2\pi} \\ &= \frac{1}{2\pi} + \int_{-\pi/2}^{\pi/2} (K(\theta,\phi) - \frac{1}{2\pi})p(\phi)d\phi \end{aligned} \tag{4}$$

where K is the probability of taking the direction ϕ when the current direction is θ due to the random perturbation R. For instance, if R is Gaussian, then K is a Von Mises distribution centered in θ, i.e. $K(\theta,\phi) = \frac{e^{cos(\phi-\theta)}}{2\pi I_0(1)}$ with $I_0(x)$ the modified Bessel function of order 0.

However, no closed form can be obtained for $p(\theta)$. The main advantage of the Markov model proposed in this section is thus to allow making predictions on the behavior of an MBR controlled agent, using simple in analytical formulae, without lengthy Monte Carlo simulations.

4 PRACTICAL EXPERIMENTS

Previously reported simulation experiments [3] show that the application of MBR is not restricted to the simple 2D case described beforehand. In particular, it was shown that MBR is able to increase the evaluation function E_t of systems with dynamics

$$x_{t+1} = f(x_t, u_t, \ldots, u_{t-d}) \tag{5}$$

even when $x_t \in \mathbb{R}^n$ $u_t \in \mathbb{R}^m$ with n and m in the order of 40 or more dimensions. It was also shown that the function f can be a nonlinear function of the previous inputs $u_{t-1}, \ldots, u_{t-d}$, and in particular, even when a dead time is present in the system, i.e. $x_{t+1} = f(x_t, u_{t-d})$.

To test the MBR approach in a real world setting, we employed the biologically inspired robot arm shown in Fig. 4. This arm has 7 degrees of freedom driven by 17 McKibben pneumatic muscles. Each muscle is equipped with a pressure sensor, used for closed loop pressure control.

The robot is controlled by setting the variation of the pressure in each of the 17 pneumatic actuators, i.e. $u_t \in \mathbb{R}^{17}$. The task chosen consists in reaching repeatedly three targets in the robot reachable space. These targets are located at the robot's right, left and bottom part of the reachable space.

To verify the robustness of the approach to sensory input noise, we tested three ways of measuring the end effector position, from which the function E_t is computed:

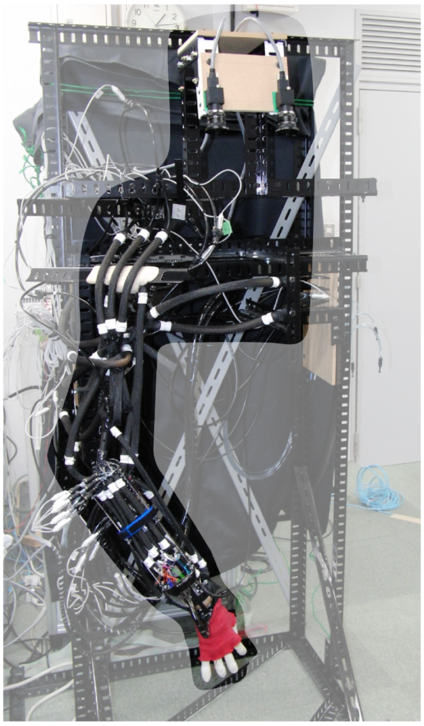

Fig. 4. The robot arm used in the experiment.

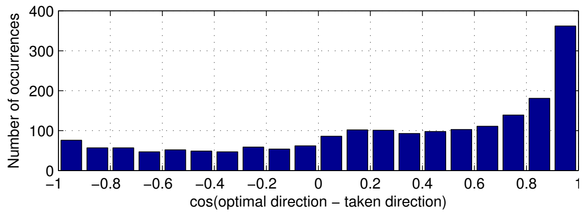

Fig. 5. Frequency of the cosine between the direction taken by the MBR-controlled robot arm and the direction straight to the target location.

1. A four dimensional vector composed by the end-effector centroid in the images of the two cameras mounted on the robot's head.
2. The three dimensional position of the end effector, obtained using stereo computation.
3. A three dimensional position of the end-effector observed by a motion capture system (EvaRT, Motion Analysis Ltd.)

The task could be achieved with all the three types of the information, showing the adaptability and the robustness of the approach. We note that the value of η was chosen empirically, without fine tuning, and kept constant in all the settings. In fact, although not optimal, any $\eta \neq 0$ can be employed for achieving the task.

The real world experiment is different for many points compared with the system analyzed in Section 3: the dimensions of the input command u, of the space x, the mapping between u and x, the noise in the sensory system, etc. Nonetheless, as Fig. 5 shows, the distribution of the cosine between the optimal direction (straight to the target) and the direction taken by the robot during the whole experiment is a decreasing function, as predicted by our simplified model.

5 CONCLUSIONS

In this paper we proposed a Markov chain model to study MBR, a simple, biologically inspired algorithm for robot control. We showed that the algorithm is able to drive a pneumatic robot arm's end-effector to desired targets without any knowledge on the mapping between the control signal u and the resulting evaluation function variation ΔE_t or on the directions taken by the links when each muscle is contracted. We analyzed the distribution of the cosine between the optimal movement and the direction actually taken by the robot, and showed that the probability is a decreasing function of the angle, as predicted by our model, despite the numerous differences between the model and the real world setup.

Future works will need to define policies for changing η online and maximize the performances. We note that starting with a high η and decrease it over time, as in Simulated Annealing, may allow obtaining solutions with high precision (due to a low final η) in a short time (due to an initially high η). However, estimating an appropriate time constant for the adaptation of η is very complex. In fact, this depends on how fast the optimal u changes, which, in turn, depends both on the evaluation function E and on the system dynamics f.

We note that, despite the similarities, MBR presents advantages over classical Simulated Annealing. MBR does not require a good estimation of the evaluation function, but only a binary value specifying if it is increasing or not. Furthermore, it does not need to return to the one state x_t after noticing that x_{t+1} is a less favorable state. This is fundamental when dealing with real word robots of unknown dynamics. Comparison of the two algorithms in real world setups is, however, an important point to be focused in the future.

Control method for a redundant robot using stored instances

Yuya Okadome[1], Yutaka Nakamura[1], and Hiroshi Ishiguro[1]

[1] Department of Systems Innovation, Graduate School of Engineering Science, Osaka University, 3-1 Machikaneyama, Toyonaka, Osaka, Japan. okadome.yuya@irl.sys.es.osaka-u.ac.jp

Abstract: A robot operating in a real environment, as opposed to industrial robot working in factory, must have the exibility to cope with disturbances and irregular factors. In this paper, we propose a control method where the control signal is selected from past experiences (stored instances) of a similar situation, according to the evaluation of each instance. We apply our method to the control of a robot with complicated structure, driven by several elastic actuators. Experimental results show that the control of a robot with many DOFs can be achieved by the proposed method.

Keywords: adaptive control, k-nearest neighbor, redundant robot

1 INTRODUCTION

In order for a robot to work in a real environment, the robot has to have the ability to cope with various kinds of situations. A robot with many DOFs is advantageous since it can generate various behaviors, and thus it is expected to have the ability to adapt to various situations. A learning method such as system identi cation or reinforcement learning can be applicable to the control of such a robot; however, this is di cult due to its complexity especially when its dynamics are in uenced by various environmental factors. For example, system identi cation methods using piece-wise linear functions [4][7] to approximate the dynamics of the controlled target have been successfully applied to the control of a robot, but a huge number of pieces becomes necessary to approximate such complex dynamics.

Autonomous learning methods such as reinforcement learning might also be applicable to the control of this type of robot, in principle (e.g. Actor-Critic[1][5] algorithm or Q-Learning[3][6]), but the application becomes di cult in case of controlling a robot with many DOFs. One of the most di cult problems is the increase in the number of parameters to be learned. In order to determine a large number of parameters, it is necessary to obtain a huge number of data (i.e. the curse of dimensionality). Besides, the amount of available data does not increase even though the dimensionality of the dynamics of the target system does increase, resulting in longer operating time and more troubles.

In this paper, we propose a control method using stored instances. In this method, a certain number of instances in the database, similar to the current state, are evaluated based on experience, and one of the instances among them is selected according to this evaluation. The control signal is determined from the selected instance. Since the control signal is determined from the database directly, an explicit modeling of the control target is not necessary. That is, this method is a kind of non-parametric method and uses the knowledge of the system implicitly included in the dataset to determine the output. Note that further knowledge about the system cannot be obtained from the database even if a system identi cation method is used.

2 CONTROL METHOD USING STORED INSTANCES

In this research, we propose a control method where the control signal is directly determined from the stored instances. Since this method does not employ a system identi cation nor a learning method, it is advantageous if the control target has a redundant structure which makes the learning of the system di cult.

2.1 Gathering Instances

To obtain instances for determining the control signal, the robot is controlled by randomly generated control signals at rst. During this procedure, the controller observes the current state of the robot $\boldsymbol{x}(t)$ and output the control signal $\boldsymbol{u}(t)$ at random. A pair consisting of the state and the control signal $\boldsymbol{d}_i = \{\boldsymbol{x}(t=i), \boldsymbol{u}(t=i)\}$ is called "an instance" and added to the database.

Each instance in the database D is denoted by $\boldsymbol{d}_i$ for the understandability of the notation and the database is de ned as a set of instances:

$$D = \{\boldsymbol{d}_i |\ i = 1, 2, \ldots, N\} \quad (1)$$

where N is the number of instances. Note that $\boldsymbol{d}_{i+1}$ is the instance composed by subsequent state and action of the i-th instance $\boldsymbol{d}_i$.

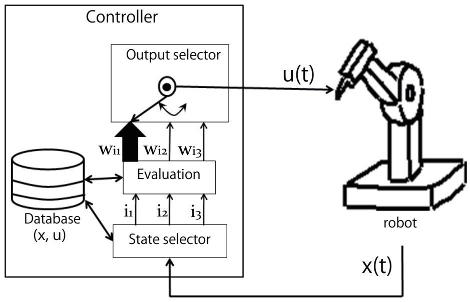

Fig. 1. Block diagram of proposed method

2.2 Control Rule

Fig. 1 shows a block diagram of the proposed method. After the controller observes the state $\boldsymbol{x}(t)$, nearest K neighbors in the database are selected by the "state selector". Indexes of nearest K instances constitute the set "KNN".

We employ a simple evaluation function, where the weight of each instance is determined from the distance between the trajectory starting from each instance in the KNN and the given goal. Thus, the weight of the i-th instance ($i \in KNN$) is de ned as:

$$w_i \quad = \quad \min_{j<p} \{||\boldsymbol{G} \quad \boldsymbol{d}_{i+j}||_2\} \tag{2}$$

where p is the length of the trajectory to be considered in the evaluation, and $\boldsymbol{G}$ denotes the goal state. $||\boldsymbol{G} \quad \boldsymbol{d}_{i+j}||_2$ is the Euclidean distance from the state $\boldsymbol{x}_{i+j}$ of the $i+j$-th instance.

After the evaluation for all instances in KNN, one of the KNN instances is selected by the control signal selector. The probability to select the i-th instance is

$$P(i) = \begin{cases} \frac{\exp(w_i T)}{\sum_{j=1}^{K} \exp(w_j T)} & i \in KNN \\ 0 & \text{otherwise} \end{cases} . \tag{3}$$

T is a parameter called inverse temperature which modi es the probability. When T is large, the instance with maximum weight is selected almost deterministically. On the other hand, when it is small, every instance can be selected with equal probability.

3 CONTROL OF ELASTIC BINARY MANIPULATORS

We applied the proposed method to a control task (reaching task) of a redundant robot (Fig. 2). This robot is a variation of binary manipulators [2] with elastic links.

3.1 Elastic Binary Manipulators

The Elastic Binary Manipulators has several links with a truss-like structure. As seen in Fig. 2, each link (line) and joint (black point) is modeled by a spring damper without mass, and a mass-point, respectively. The control signal to the robot consists of the natural lengths of the links, and changes the equivalent point (posture). In the simulation, the natural lengths of the 12 links represented in the gure by dashed lines can be changed according to the control signal, and the others are xed. The length of each variable link can have a larger or smaller value and the former is 1.5 times longer than the latter.

The force applied to the i-th mass-point is de ned by:

$$\boldsymbol{F}_i \quad = \quad \sum_{j \in C_i} \left\{ \quad k(l_{ij} \quad \bar{l}_{ij}) \frac{\boldsymbol{s}_i \quad \boldsymbol{s}_j}{||\boldsymbol{s}_i \quad \boldsymbol{s}_j||_2} \quad D(\boldsymbol{v}_i \quad \boldsymbol{v}_j) \right\}, \tag{4}$$

$\boldsymbol{s}_\iota$ and $\boldsymbol{v}_\iota$ denote the position and the velocity of the ι-th joint. l_{ij} and $\bar{l}_{ij}$ are the current length and the natural length of the link connecting the i-th and the j-th joints. k and D are the spring and the damping constants.

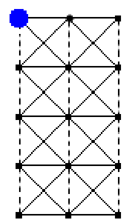

Fig. 2. Structure of the EBM

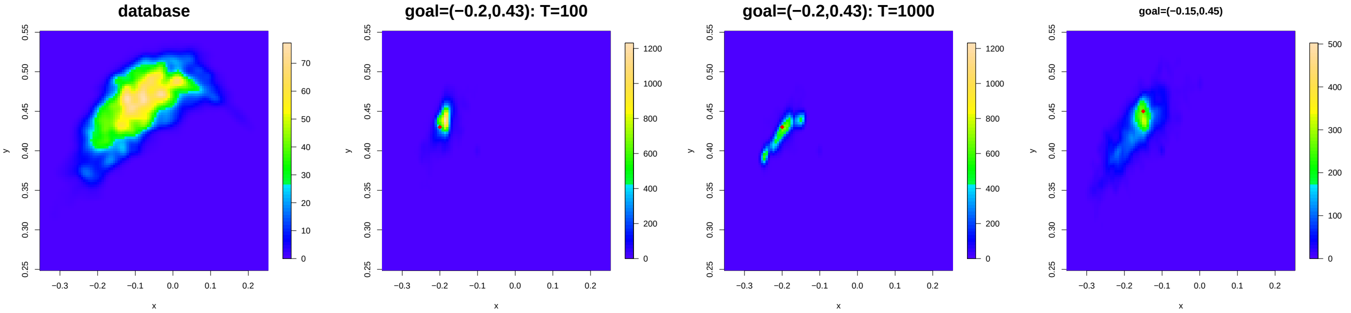
3.2 Reaching task

The purpose of the reaching task is to move the ende ector (blue point) to the goal position. During the instance-gathering phase (500,000 time steps), 6 links are selected randomly and their natural lengths are altered (small to large/ large to small) every 1,000 time steps. To generate meaningful motions, the control signal is maintained over a certain time period (1,000 time steps).

We conducted experiments with the goal G = (0.2, 0.43). K was set to 5 and T was set to 100 and 1,000. These values were determined by trial and error.

Fig. 3(a) shows the density of state-instances stored in the database visualized by a kernel density estimation method. Fig. 3(b) and Fig. 3(c) show the density of the state while performing the reaching task. The yellow-colored area indicates that the end-e ector stays



(a) (b) (c) (d) with broken link

Fig. 3. Result of reaching task: Elastic Binary Manipulators

in these areas for a long time. The red point in each gure represents the goal position of the reaching task, and it can be seen that the density concentrates to the area close to the goal in both cases. These results show that our control method allows the robot to achieve the reaching task. The performance of the case $T = 1000$ is worse than that of $T = 100$. This suggests that stochastic choice of control signal makes the robot escape from the local optima.

We conducted an additional experiment to investigate whether our method can exploit the redundancy of the robot (Fig. 3(d)). Even when a controllable link is broken (the natural length is xed), the proposed method allows the robot to achieve the task if there is a link which is able to compensate the broken link.

4 CONTROL OF HUMAN-LIKE ROBOTIC ARM

We applied the proposed method to a control task of a human-like robotic arm (Fig. 4). We conducted a reaching task by this robot.

4.1 Human-Like Robotic Arm

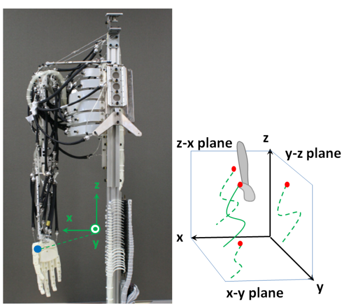


Fig. 4. Human-Like Robotic Arm

The human-like robotic arm consists of 6 links and has a high degree of freedom (9-DOFs). More than 30 pneumatic actuators (arti cial muscles) are connected to these links, and are controlled by 26 air- ow control valves. Each actuator expands (contracts) when the air pressure decreases (increases). Actuators are located at positions similar to those of human muscles. The air ow of each valve monotonically increases according to the control signal, i.e. the output of the D/A converter (output range: 0 6[V]). To control this robotic arm, it is necessary to determine the control signal consisting of 26 analog values depending on the state of the robot.

4.2 Reaching task

The purpose of the reaching task is to move the hand (represented by the blue point in Fig. 4) to the goal position. During the instance-gathering phase (1500[s]), 13 actuators are selected randomly and their input values are altered randomly in every 1[s]. We conducted two experiments with two di erent goals, $G = G1(0, 150, 140)$ and $G2(\ 40, 100, 80)$. In each reaching task, the operation time was 150[s] and the control signal is altered once in 0.5[s]. K and T were set to 10 and $\frac{2}{15}$ by trial and error.

Fig. 5(a) and Fig. 5(b) show the density of the hand position in the database. Fig. 5(c) Fig. 5(f) show the densities of the position of the hand during the reaching tasks projected on the X-Y and X-Z planes. The red point in each gure represents the goal position, and we can see that the density concentrates to the goal in both cases. These results show that our control method allows the robot to achieve the reaching task.

Reaching G2 seems worse than in the case of G1, since the density spreads widely. If there are fewer instances approaching the goal in the database, it is dif- cult to achieve the task since such a instance is often cut o from the k-NN. The reason why reaching G2 is more di cult is that there are fewer instances useful for achieving the task.

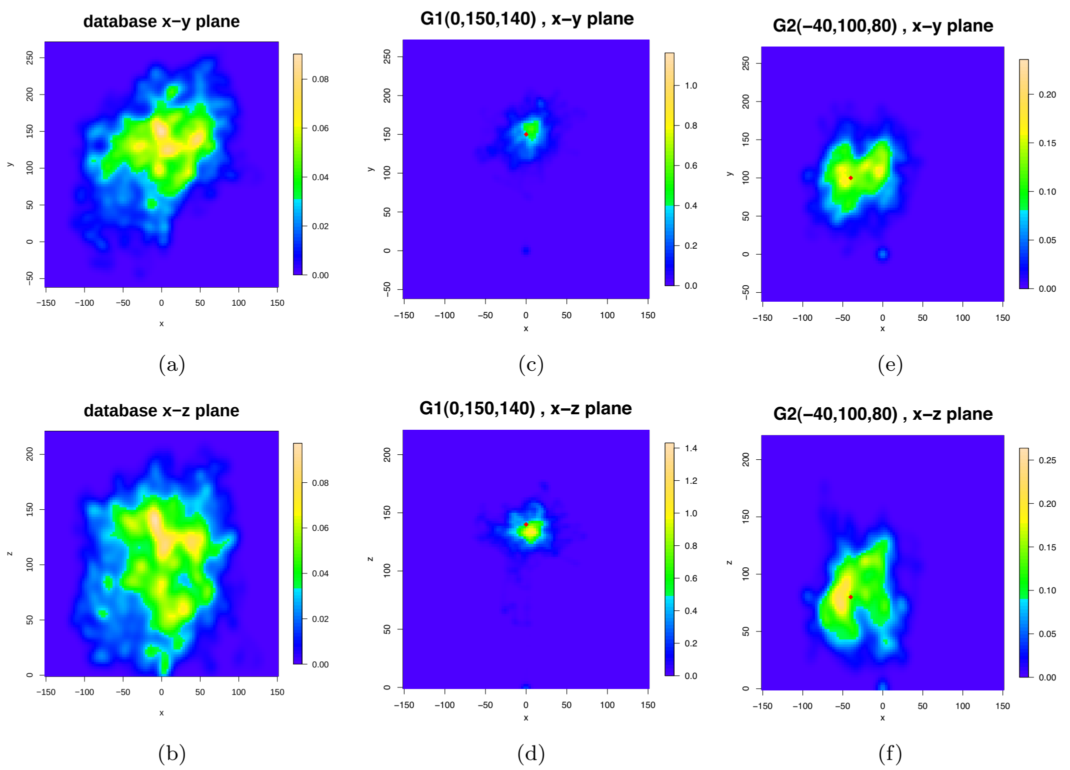

Fig. 5. Result of reaching task: Human-Like Robotic Arm

5 CONCLUSION

In this paper, we proposed a control method using stored instances which does not need an explicit modeling of the control target. We applied the proposed method to the control tasks of redundant robots and showed that the reaching task can be achieved by our method.

One of the problems of our method is performance degradation due to the bias of the distribution of the instance in the database. To overcome this, it might be useful to omit similar instances from the database or employ an importance sampling method. To develop a method for adding the instances in an online manner is also part of our future work.

Abstract: In this paper, we propose a multi-legged robot that is designed for operating on rubble. Generally, conventional multi-legged robots have many actuators for driving the legs and body. Hence, control in the case of these robots is more complicated than that in the case of crawler robots, and it is very difficult to operate multi-legged robots adaptively in a complex environment like rubble. To solve this problem, we have designed a mechanism of the legged-robot for reducing the controller load by utilizing a passive mechanism. To design the robot, we focus on a centipede. First, we observe the behavior of a centipede by using a high-speed camera, and then, to realize this behavior by a simple mechanism, we propose a multi-legged robot that is realized by connecting many links serially through rubber joints. In this mechanism, every joint has a leg on both sides, and the robot moves regularly like a centipede. The elasticity of the rubber joints compensates for the bumps on the ground. To control the moving direction, wires are installed through the links, and by pulling the wires, the body of the robot can be lifted up or turned. By simply pulling the suitable wires, we can control the moving direction of the robot. We do not have to control many joints individually for crossing bumps. They can move passively and can cross the bumps. To demonstrate the effectiveness of the proposed robot, we have developed a prototype robot and conducted certain experiments. The results show that the robot can move on rubble to desired positions.

Keywords: multi-legged robot, centipede, passive mechanism.

1 Introduction

Recently, robots that operate in complex real environments, for example, rescue robots, agriculture robots, and forestry robots, have attracted considerable attention. Hence, various robots that have high mobility have been developed [1-6]. Usually, conventional robots have many crawlers to realize high mobility and can overcome various obstacles like steps, bumps, and dents. However, crawlers have two disadvantages in a real environment. One is the slip on a low-friction ground like dry sand, and the other is the locking of crawlers owing to the engulfment of wires, long grasses, etc.

On the other hand, legged robots can solve these problems of crawlers and have relatively high mobility in these situations. Therefore, the development of effective multi-legged robots for complex real environments is expected.

However, in general, multi-legged robots have many actuators for driving their legs and body. Hence, control in the case of these robots is more complicated than that in the case of crawler robots, and it is very difficult to operate multi-legged robots autonomously in complex environments like rubble. This is a major disadvantage of multi-legged robots.

In this study, in order to solve this problem, we have designed a mechanism of the legged-robot for reducing the controller load by utilizing the passive mechanism proposed in our previous work [6]. To design the robot, we focus on a centipede. We observe the behavior of a centipede by using a high-speed camera, and then, to realize motions similar to those of a centipede by using a simple mechanism, we propose a multi-legged robot that is realized by connecting many links serially through rubber joints. To demonstrate the effectiveness of the proposed robot, we develop a prototype robot and conduct experiments.

2 Centipede

We observed the behavior of a centipede by using a high-speed camera. Fig. 1 shows a photograph of centipede motion over rubble, and Fig. 2 shows the locomotion pattern.

No. 1 No. 2 No. 3

No. 1

No. 2

No. 3

No. 4

Fig. 2. Locomotion pattern

We can see that the legs of the centipede move regularly in wave-like motions from the front to the rear part. However, the legs are not rigid and they adapt to the bumps on the ground while maintaining the wave-like motion. Further, the centipede changes its moving direction by lifting or turning its body. In this study, we aim to realize a similar behavior by using a simple mechanism.

3 Proposed mechanism

Fig. 3 shows the proposed mechanism for realizing the centipede-like behavior.

The multi-legged robot is realized by connecting many links serially through rubber joints (Fig. 3 (a)). Every link has a leg on both sides (Fig. 3 (b)), and each leg has two joints. The legs are moved regularly like those of a centipede by using feedback controllers. To control the moving direction, wires are installed through the links (Fig. 3 (c)), and by pulling the wires, the body of the robot is lifted up or turned as shown in Fig. 4. By simply pulling the suitable wires, we can control the moving direction of the robot. We do not have to control many joints individually for crossing over bumps because the elasticity of the rubber joints compensates for the bumps on the ground. These joints can move passively and can cross the bumps.

Fig. 5. Developed robot

This robot has six links and twelve legs. Each link has two legs that are actuated by one motor (Fig. 5 (a)). The motion of the legs is realized by a link mechanism, as shown in Fig. 6. Each link has one potentiometer (Fig. 5 (b)) to detect the rotating angle, and one controller is employed per link for controlling the phase between the former leg.

No. 5 No. 6

Fig. 9. Movement over rubble

From Fig. 9, we can confirm that the body of the robot moves adaptively to the environment and can move over rubble despite the fact that the operator controls only three wires and many five joints of the body moved autonomously by using the dynamics of the real world.

6 Conclusion

In this study, we designed the mechanism of a legged-robot for reducing the controller load by utilizing a passive mechanism. To design the robot, we focused on a centipede and observed its behavior by using a high-speed camera. To realize centipede-like motions by a simple mechanism, we propose the use of rubber joints. We employed a wire for controlling the body movements. To demonstrate the effectiveness of the proposed mechanism, experiments were conducted, and the behaviors required for moving over rubble were realized.

In a future study, we shall examine the use of the proposed mechanism in practical applications, for example, in a rescue mission for searching for survivors on large disaster sites.

Construction of a sense of force feedback and vision for micro-objects:

Recreate the response and a sense of force of objects

Abstract. The purpose of this research was to develop a combined sense system that uses both force feedback and visual feedback to determine the shape of the microscopic features of a microsample. Efficiency in performing minute procedures would be improved if the operator could have a sense of force while using a manipulator. We used a cantilever to touch a minute object and obtain a reaction force from the degree of bending. We constructed a haptic device that gives a sense of that force to the operator when touching the sample with a cantilever. When the haptic device was used in simulations, the user could feel a force as if he had touched the sample.
Key words: force feedback, haptic interface, simulation.

1. Introduction

Technologies that can accurately perform minute work are now being sought for medical treatment and in the field of manufacturing semiconductors. Such minute work is improved by using micromanipulators, but their operation is difficult because the operator has no sense of force; he or she relies only on sight through a microscope. As a result, a person skilled in the use of this technology is needed for all minute work. The efficiency of minute work would be improved if the operator were able to have a sense of force while using a manipulator.

Here we describe the development of a more efficient system for minute operations. Our aim was to develop a system using not only the sense of sight through a microscope but also a sense of force from the manipulator. For this fundamental research, a system was created to assess the reaction force when a minute sample was touched. A cantilever was used to touch the sample, and the reaction force was obtained from the degree to which the sample bent. In addition, we used a haptic device and amplified the force feedback from a minute sample of a virtual object.

2. System Structure

2-1. System summary

The system structure is shown in Fig. 1a, and a schematic view is shown in Fig. 1b. This system consists of a microscope with an automatic x-y stage, a piezo stage, a feedback stage controller to control the x-y stage, a piezo stage controller, a haptic device for transmitting force feedback (Fig. 2), a cantilever (Fig. 3), and a PC via which the user can control and operate these components. The sample was fixed on the x-y stage by an injector (Fig. 4) and a holding pipette (Fig. 5). When the cantilever, which was fixed to the piezo stage, touched the sample, the operator could maintain the cantilever's position by obtaining the value of the reaction force through the interface. The resolution of the piezo stage is 1 nm.

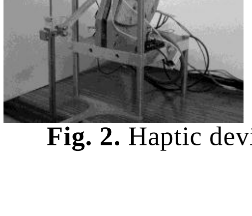

Fig. 2. Haptic device.

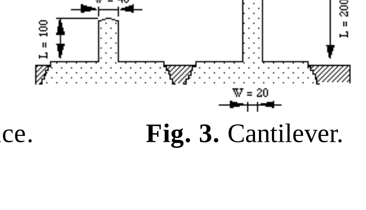

Fig. 3. Cantilever.

Fig. 4. Injector.

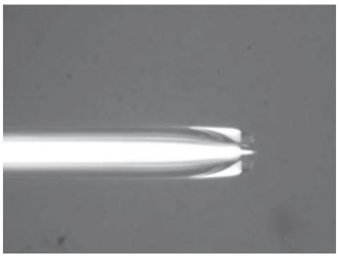

Fig. 5. Tip of holding pipette.

2-2. Haptic device

Figure 6 provides a diagram of the haptic device. It consists primarily of a rotor, a laser, and a position-sensitive device (PSD). We installed a coil on the rotor with a polarity magnet, which generated electromagnetic induction by an electric current and a magnetic force. The angle of the rotor can be measured by the laser and the PSD. The rotor was able to follow any input waveform.

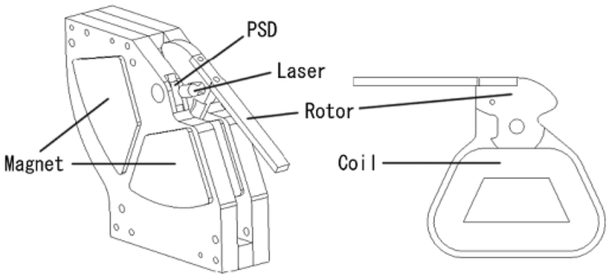

Fig. 6. Diagram of the haptic device.

The actuator is controlled by a servomechanism on the actuator. The system driving the actuator therefore consisted of four actuators: a microcomputer, an inputting AD/DA port, an outputting microcomputer, and a PC outputting order value. The system controls the actuator during each part of the process. Figure 7 shows the structure of the haptic device.

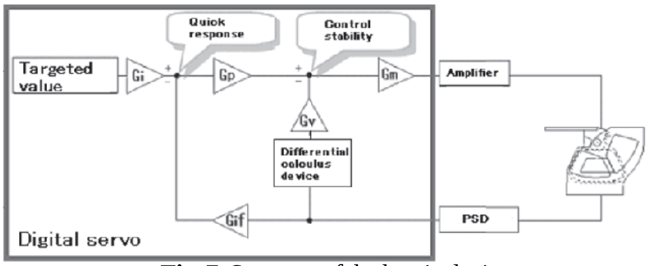

Fig. 7. Structure of the haptic device.

The actuator, whose actions are governed by the PD control, is operated through a digital differential calculus device. A transfer function for the quadratic function system shown in Fig. 8 is provided for the actuator servo system. The role of each parameter of the control system is to adjust the total offset to a master in Gi/Gif, to regulate the item viscosity/resonance point in Gp/Gv, and to regulate the total gain in Gm. Table 1 provides a list of the control parameters of the servomechanism system.

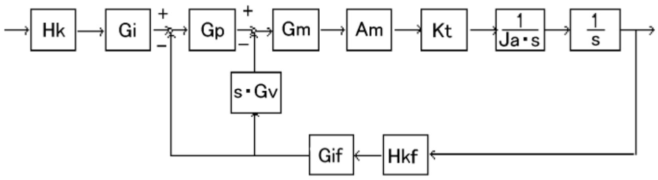

Fig. 8. Block diagram of the servomechanism system.

Table 1 Control parameters of the servomechanism system

Parameter	Reference	Unit
Hk	Position Voltage Constant	18.56 [V/rad]
Hkf	Position Voltage Feedback Constant	18.56 [V/rad]
Am	Amplifier Constant	0.8986 [A/V]

Ja	Moment of Inertia	0.000581 [kg·m]
Gi	Controller Input Gain	1
Gif	Position Feedback Gain	1
Gp	Position Gain	adjusted value
Gv	Velocity Gain	adjusted value
Gm	Manipulation Gain	1

3. Measuring the reaction force

The reaction force was used to calculate the force applied by the minute object. In this experiment, we touched the minute object with the cantilever shown in Fig. 3, and the reaction force was obtained based on the degree of bend of the cantilever. The layout of the experiment is shown in Figs. 7 and 8, and the environment of the experiment is shown in Figs. 9 and 10. Based on this experiment, we were able to determine the reaction force applied by the minute object.

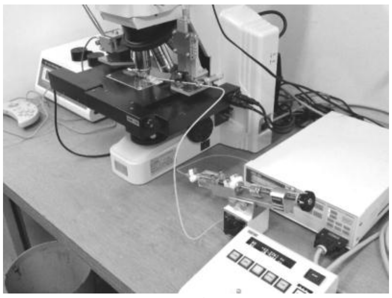

Fig. 9. Environment of the experiment.

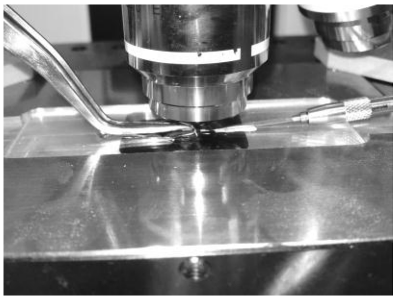

Fig. 10. Close-up of the environment of the experiment.

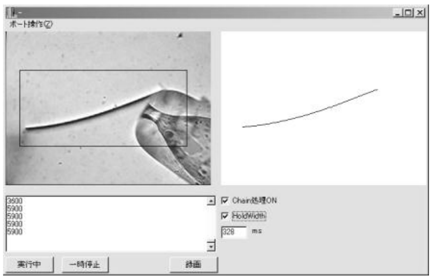

Fig. 11. Cantilever touching the tip of the holding pipette.

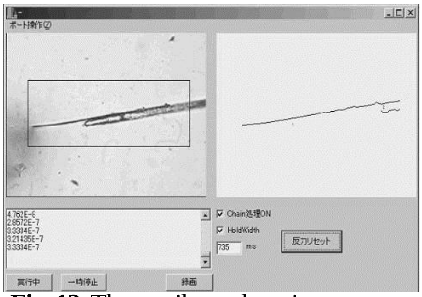

Fig. 12. The cantilever detection program.

Figure 11 shows the cantilever touching the tip of the holding pipette. Figure 12 shows the experiment that measures the reaction force of the downy hair. The image-processing speed of the cantilever was improved by the tracking process. The bend of the cantilever is assumed to be linear-elastic so that Hooke's law may be applied. The restoring force, F, of the bend of the cantilever is given by

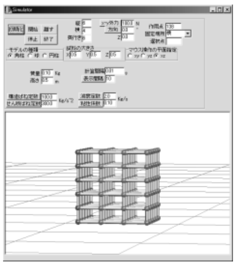
$$F = kx \tag{1}$$

where *x* is the compression distance from the equilibrium position, and *k* is the spring constant.

4. Deforming the sample in simulation

In this study, we attempted to build a working system using a microscope, a haptic device, and a simulation. A fundamental element was simulating the deformation of a minute object. Figure 13 shows the graphical user interface (GUI) of the simulator. A graphic tool was created using OpenGL to draw the object and to choose the shape of the sample, for instance, a cube or sphere. The dynamic model of the sample consisted of a spring-mass array of mass points in both the vertical and horizontal directions. An example of the arrangement of mass points is shown in Fig. 14. When a force was applied at a mass point, the simulation calculated the speed of all mass points that had been affected. The image was renewed after every ten calculations.

We defined a spring as having a size but no weight, and a mass point as having a size, a weight, and a rigid body. An arbitrary mass object can be placed on a spring on a bitmap (Fig. 15). In addition, a sample can be seen from various viewpoints, and the deformation of the sample, which is impossible to observe by microscope, can be checked. The shape of this object can be either a cube or a sphere, and any point may be selected as a fixed point or an operating point.



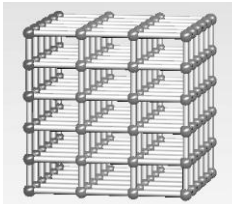


Fig. 13. Simulator.
Fig. 14. Arrangement of mass points

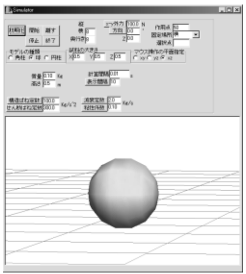

Fig. 15. Placing an arbitrary object on a bitmap.

The calculation method for the displacement of each mass point is based on Newton's equation of motion (Eq. 1) using the Euler method. A mass point is linked to an adjacent mass point at both ends of a spring. When the spring between the mass points is in the equilibrium position, the restoring force, F, is the sum of the elastic force of the construction spring and the shear spring, and the viscous force is given by

$$ma = \Sigma F \tag{2}$$

where m is mass and a is acceleration.

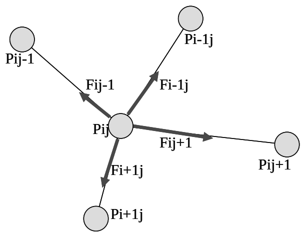

Fig. 16. Elasticity.

ΣF is the sum of the elastic force of the construction spring and shear spring, the viscous force, and the damping force. To obtain F, we divided the restoring force into $F_{damping}$, F_{spring}, and $F_{viscous}$. Equation 2 gives the following equations using the model shown in Fig. 16:

$$F_{spring} = \Sigma F_{ij} \tag{3}$$

$$F_{damping} = -C_d v_i \tag{4}$$

$$F_{viscous} = -C_v (v_i - v_j) \tag{5}$$

$$\Sigma F = F_{spring} + F_{damping} + F_{viscous} \tag{6}$$

where C_d is the damping factor, C_v is viscosity, and v_i and v_j are the velocities.

5. Characteristic measurements and a reappearance experiment for an object

Dynamic and static characteristics of the object were measured and then recreated using the haptic device. The object used this time was silicon manufactured by KYOUTOKAGAKU. The silicon sheet thickness was 2 or 3 [mm]. Each characteristic when silicon was stacked up was measured. Figure17 shows the response of the silicon and the response of the haptic device. Figure18 shows the reaction force of the silicon and the output power of the haptic device.

In the last program, parameters cannot be changed during operation. However, the response of the silicon used for the experiment in this case was could not recreate one parameter, and the sense of force was not linear. Therefore, the program was implemented so that parameters could be changed during operation.

Table 2 shows the frequency, constant of spring, and damping coefficient in each ectopic focus when the dynamic characteristic is recreated. Table 3 shows the frequency and constant of spring in each ectopic focus when the static characteristic is recreated.

The characteristics recreated by the haptic device, and the experiment was evaluated. In this experiment, there was a tendency for a touch feeling close to that of real silicon to be created when the static characteristic was recreated.

6. Conclusion

In the present study the characteristics of silicon were measured and recreated, and evaluations were carried out with regard to response and sense of force using a haptic device. The touch judging program of the haptic device and sample simulation was implemented. It was found that the spring constants differed greatly with regard to both dynamic and static characteristics in this experiment. The characteristics of various objects will be measured in the future, and The characteristics recreated

Future research should focus on building a system that allows a reaction force to be detected and shown more precisely. Such a system would make it possible to test smaller samples.

Abstract: Recently, reinforcement learning (RL) attracts attention. Because interaction with environment is important on RL, it is necessary to recognize state of robots more accurate. However, in real environment there is incompleteness on recognition by ability lack and noise of sensors. If recognition has incomplete, there is problem that robots cannot learn appropriately because robots cannot distinguish states that robots should originally distinguish. The model including such incompleteness is known as POMDP and we aim to solve the problem learning does not progress appropriately in POMDP. We pay attention to the experience of robots. When robots cannot identify current state uniquely, robots decide current state using current observation, previous recognition state and action. And, by memorizing this state information as internal state, recognizable state increases. In this way, robots can distinguish states which robots cannot distinguish in conventional method and learn appropriately. We show the effectiveness of proposed technique with simulation.

Keywords: Reinforcement Learning, Partially Observable Markov Decision Process, incomplete recognition

1 INTRODUCTION

Now, RL [1] is known as effective technique as one of technique to adapt to environment. RL also attracts attention as technique which is often used in actual robots. On RL, robots learn by interaction with environment. And sensors are necessary for interaction with environment. Robots recognize a situation as a state that robot faces by using sensors. So the recognition by sensors is important for learning.

In RL, most basically model of environment is Markov Decision Process (MDP) [2]. In this environment, it is assumed that the recognition of environment by robots is complete. In other words, robots have enough recognition ability to achieve tasks in MDP. But in real environment, because the ability of sensors is insufficient or sensors have noise, there is often incompleteness for recognition. So, recognized state does not accord with actual situation. Partially Observable Markov Decision Process (POMDP) [3] is model that deals with such incompleteness. In POMDP, robots may recognize different plural situations in real environment as same state. Because robot recognizes different situations as same state, there is possibility that robot cannot learn appropriately for task. So, there are some studies for environment on POMDP [4],[5].

In this paper, we pay attention to using past state and action. And we propose a system coping with incomplete recognition. In proposed system, robot recognizes a current state by using previous state and action. Not always robot recognizes state by using such technique, but robot recognizes current state by using previous state and action at the time that robot recognizes incomplete recognition. Therefore robot needs to recognize whether current state is incomplete recognition. We use experience of robots for recognition of incomplete recognition. In experience on robot, when there is difference on result of same action between same recognized state, incomplete recognition is likely to have occurred. In the case that there is difference from two results of same action on a recognized state, robot define internal state for the state by using previous state and action. And robot can distinguish a state thought to be incomplete recognition by using internal state. Therefore it is possible to consider POMDP to be MDP by using proposed method. And proposed system has four parts: Recognition part, Judgment of incomplete recognition part, Definition of internal state part, and Accumulation of experience part.

In this paper, at first we describe the summary and problems about recognition in POMDP on RL. Secondly we propose the technique of recognition using previous state and action. We will describe four parts of Recognition part, Judgment of incomplete recognition part, Definition of internal state part and Accumulation of experience part. Thirdly, we perform simulation that shows the effectiveness of proposed system. In simulation, we use the maze problem and adapt Q-learning[1] to agent. Moreover, we compare the proposed technique with normal recognition and complete perception. Finally, we describe conclusion and the future work.

2 PROBLEM OF RECOGNITION IN POMDP

2.1 Recognition using sensors on RL

The subjection of our research is a learning agent which has sensors. On RL, at each time period, the agent is in some state $s \in S$ (S is a set of states). But the agent recognizes a state that agent faces through sensors. On recognition based sensors, the agent decides a state by the combination of value of each sensor. Here, $o \in O$ (O is a set of observations) is an observation that agent recognizes through sensors and v_n are value of each sensor. o is expressed in eq.(1), and n is number of sensors agent has.

$$o = \{v_1, v_2, \ldots, v_n\} \tag{1}$$

In the case of the recognition with sensors, the observation is not usually equals to the state in POMDP. And there is a possibility that the agent recognizes two or more another states as a same observation. There are various factors including performance and property of sensors for this reason to cause these, and we think it is difficult to solve the disagreement in the state and observation using only sensors.

In this paper, in case that there is disagreement in the state and the observation, we call this situation as incomplete recognition. And, in case that the observation is same as the state, we call this situation as complete recognition.

2.2 Problem by the incomplete recognition on RL

On RL, agent learn appropriate action based on the observation. Therefor the observation is important. If agent is in incomplete recognition, agent tries to find appropriate action for an observation includes several states (Fig.1). Agent can not learn appropriately, in such case. But incomplete recognition does not become the problem always. When appropriate actions for states included in an observation are the same, agent can learn without problems. In fact, when the appropriate actions for each state included in an observation are different, it adversely affects for learning. In this way, when agent is in incomplete recognition, it is possibility that agent can not learn appropriately. And it is need to distinguish several states included in an observation for such agent.

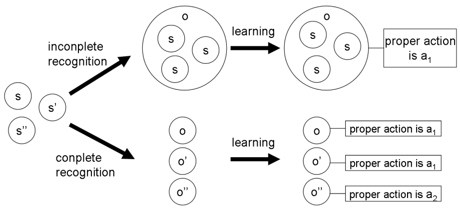

Fig. 1. The relationship of recognition and learning.

3 SUGGESTION OF RECOGNITION TECHNIQUE FOR POMDP

3.1 Estimate of state with previous recognized state and action

When incomplete recognition gives adverse affect for learning, agent should distinguish an recognition state (recognition state is state that agent finally decide) causing incomplete recognition as plural states by subdivision of recognizable state. So, when subdividing an recognition state that is causing the incomplete recognition, we focus on the pair of previous recognition state and action. Specifically when agent is in incomplete recognition at an recognition state, agent subdivides the recognition state by referring to the pair of previous recognition state and action (Fig.2). The subdivided observations are defined new internal state. And this internal state is held as knowledge by addition to X (X is a set of internal states). We define the internal state x in eq.(2). Here, $\hat{o}_t$ is an recognition state at time t, $\hat{o}_{t-1}$ is a recognition state that agent decide at time $t-1$, and a_{t-1} is an action agent takes in $\hat{o}_{t-1}$.

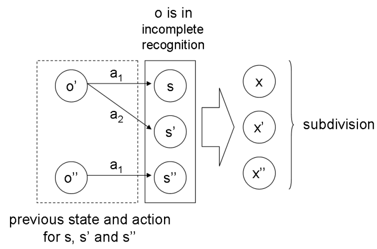

Fig. 2. The conception of estimate of state with previous recognized state and action.

$$x = \{\hat{o}_t, \hat{o}_{t-1}, a_{t-1}\} \tag{2}$$

Agent can recognize current state more particular by referring to previous recognition state and action. However, the number of the internal states that agent should experience increases, if agent subdivides an observation in all situation. It is not desirable that the number of the internal states increases for learning, because it takes much time to learn. In this paper, agent subdivides for the observation that may cause incomplete recognition. Therefore, it is need to judge whether the observation is incomplete recognition for agent. We think the observation includes plural states when a certain observation is incomplete recognition. And in this case, it is thought that different results are shown even if agent takes same action at the observation (Fig.3). Therefore, agent determines an observation that gains different result for same action as situation agent is in incomplete recognition. And we prepare the experience table to compare the results of actions. The proposed system has four original modules:

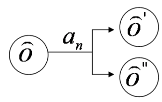

Fig. 3. The problem situation.

Recognition part to decide a internal state by using previous internal state and action, Judgment of incomplete recognition part to determine whether incomplete recognition occurs, Definition of internal state part to subdivide for observation in incomplete recognition, and Accumulation of experience part to saves experience information. And the proposed system also has two conventional modules: Learning part and Choosing action part. We show the construction of proposed system in Fig.4.

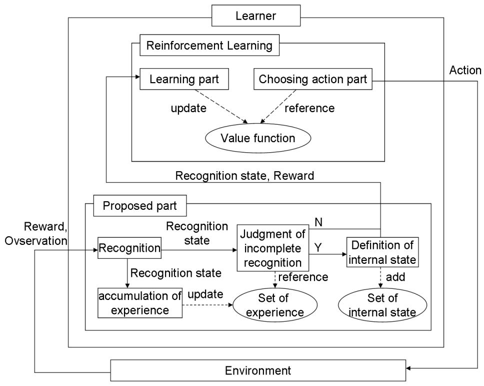

Fig. 4. The construction of proposed system.

3.2 Process of each module

3.2.1 Recognition part

In Recognition, agent decide a recognition state $\hat{o}_t$ by using current observation o_t and previous recognition state $\hat{o}_{t-1}$ and action a_{t-1}. And agent search the internal state x about $\{o_t, \hat{o}_{t-1}, a_{t-1}\}$ in set of internal state X. If agent find the internal state, agent decide x as $\hat{o}_t$. If agent can not fine the internal state, agent decide o_t as $\hat{o}_t$.

3.2.2 Accumulation of experience part

In Accumulation of experience, agent get the experience e as knowledge. This knowledge at time t is expressed in eq.3. And agent add this knowledge to set of experience E.

$$e_t = \{\hat{o}_{t-1}, a_{t-1}, \hat{o}_t\} \tag{3}$$

3.2.3 Judgment of incomplete recognition part

Agent judges whether an recognition state $\hat{o}_t$ is incomplete recognition in following procedures.

- Assume that a_t is an action in $\hat{o}_t$ and $\hat{o}_{t+1}$ is the result of action.
- Search the information about $\{\hat{o}_t, a_t, *\}$ in E
- Assume the found information as $\{\hat{o}_t, a_t, \hat{o}^{'}_{t+1}\}$
- Compare $\hat{o}_{t+1}$ with $\hat{o}^{'}_{t+1}$
- If $\hat{o}_t \neq \hat{o}_{t+1}$, agent judges that $\hat{o}_t$ is incomplete recognition.

3.2.4 Definition of internal state part

When agent subdivides a recognition state $\hat{o}_t$, a new internal state is defined in eq.2. And new internal state defined by eq.2 is add to set of internal state X.

4 SIMULATION USING PROPOSED SYSTEM FOR MAZE PROBLEM

4.1 Outline

We show the proposed system can distinguish the state enough to take task in POMDP through a simulation. We apply proposed system to an agent which recognizes state based on the sensor. And we apply maze problem to the agent with simulation. In the simulation, incomplete recognition happens when an agent decide a state by using only sensors. So the simulation is environment based on POMDP.

In the simulation, we define as one trial to reach a goal, and focus on the number of actions at each trial as the result. In addition, we prepare two agents for comparison. One is an agent deciding a state only with sensors which is same as sensors proposed system has. The other is an agent which has sensor that does not occur incomplete recognition. We unify other conditions for these three agents and apply maze problem and compare the results with these three agents.

4.2 Setting

We show the maze using the simulation in Fig.5. In Fig.5, we assume the coordinate at upper left square as (0,0), and lower right square as (2,2). The start position (●) is (0,2), and goal position ($\star$) is (2,2). In this simulation, agents fall into fatal incomplete recognition in the squares (0,1) and (1,1). Because appropriate action is difference in (1,0) and (1,1), we think it affects learning.

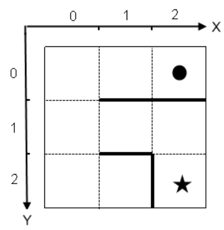

Fig. 5. The maze for simulation.

We prepare three agents (Agent-A, Agent-B, Agent-C). Agent-A and Agent-B has same four sensors. These sensors can recognizes whether there is a wall in front of sensors. Agent-A and Agent-B is set these sensors at vertically and horizontally. In addition Agent-A is applied proposed system. Agent-C own a sensor can know the coordinate in the maze And each agents select an action from four actions :move up, down ,left, right.

In this paper, we apply Q-learning to all agents as learning part. Agents learn based on eq.4 in Q-learning.

$$\begin{aligned} Q(s_t, a_t) \quad &\leftarrow \quad Q(s_t, a_t) + \alpha[r_{t+1} \\ &+ \quad \gamma \max_a Q(s_{t+1}, a) - Q(s_t, a_t)] \end{aligned} \tag{4}$$

$Q(s_t, a_t)$ is action value of a_t in recognized state s_t at time t. r_{t+1} is reward which agent gains in recognized state s_{t+1} at time $t+1$. α and γ are parameters ($0 \leq \alpha, \gamma \leq 1$). And we apply ε-greedy method to all agents as action selection part. When agent select an action, agent take random action by probability of ε and take greedy action by probability of $1-\varepsilon$. We show the parameters in Table 1.

Table 1. Setting for simulation

Reward(only a goal)	100
Total of trial	50
Initial value of Q-value	0.001
Size of maze	3×3
α	0.5
γ	0.7
ε	0.05

4.3 Result and Consideration

We show the result of the simulation in Fig.6. Fig.6 show the number of the actions for reaching the goal every trials for each agent. The X-axis expresses the number of the trials, and the Y-axis is the number of the actions that took for reaching a goal.

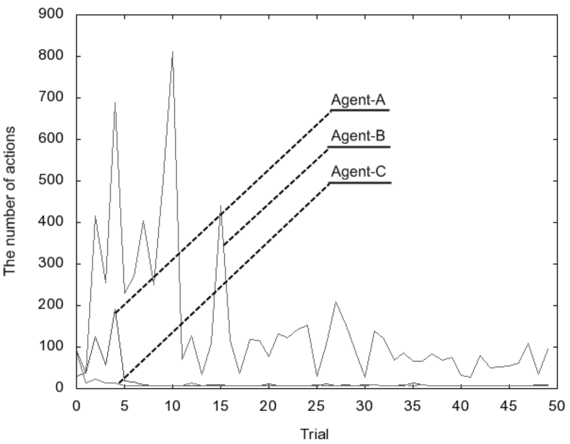

Fig. 6. Comparison of the number of actions each trial about Agent-A,B and C.

In this graph, the number of actions about Agent-B does not converge. Because Agent-B causes incomplete recognition in coordinate of (1,0) and (1,1), the agent can not learn appropriately. And the number of actions about Agent-B is bigger than other agents in all trials. Therefore, we say that incomplete recognition cases adverse affect to learning.

On the other hand, Agent-C does not cause incomplete recognition. Therefore the number of actions about Agent-C is less than Agent-A and B. Agent-C finds the most suitable route to goal by approximately five trials.

We focus on Agent-A. There are trials that there is more number of actions than Agent-C in early period of learning. However, the number of actions about Agent-A and Agent-C is almost same after 7 trials, and we think the proposed system works effectively for incomplete recognition. In proposed system, when agent causes incomplete recognition in coordinate of (1,0) and (1,1), agent distinguishes these state by subdividing the recognized state with previous state and action. Therefor, agent can distinguish enough to learn appropriately.

5 CONCLUSION

In this paper, we focus on the problem of RL in POMDP. There is a problem that agent cases incomplete recognition. And it is possibility that incomplete recognition cases adverse affect for learning. Therefor, agent can not learn appropriately in POMDP. We pay attention to previous recognized state and action for solving this problem. We proposed the recognition technique using not only sensors but also previous recognized state and action. In this way, agent can subdivide the recognized state and learn appropriately. And we proposed the system applied proposed technique to RL. We applied the maze problem to show the usefulness of the proposed system with simulation and we compared with three agents. By this simulation, we showed effectiveness of proposed system for incomplete recognition. In the future, we will apply the proposed system to actual robot.

Abstract: In this paper, we study the suitability of using simulation in the evolution of locomotion in a quadruped robot. The goal of the evolution is to design a control system that produces fast gaits. We evolve gaits in simulation, and then the best controllers are transferred into the real custom built robot and compared with their simulated versions. The results show effective locomotion, with a 1.8 times improvement in speed over earlier results. Finally, we investigate some measures to reduce the difference between simulated and real locomotion.

Keywords: robotics, simulation, genetic algorithms

1 INTRODUCTION

It can be a challenging task to manually design and optimize a control system that enables a robot to walk, particularly an unconventional robot in a complex environment. Evolutionary design allows us to automate this otherwise time consuming and intellectually demanding process [1, 2]. Furthermore, it provides a general procedure that can be applied to various robot morphologies, and can even be used for adapting to changes in the environment or in the robot itself such as damage to or loss of limbs [3]. Importantly, evolution is unconstrained by engineering conventions, and is thus able to find solutions that a human is unlikely to find.

For time-consuming tasks like robotic locomotion, it becomes impractical to perform large-scale evolutions involving tens of thousands of evaluations on the target hardware, due both to time needed and to mechanical wear. For example, in [4], a total of 1217 evaluations were performed on the target hardware, spread across 7 different learning algorithms; and as those authors point out, this number is much smaller than desirable in terms of achieving both high quality results and statistical significance, and certainly took a great deal of time to carry out. (See [5] for another such example.) To overcome this issue, evaluations can instead be performed in a simulator. With sufficient CPU power, many individuals can be evaluated in simulation in the time it would take to evaluate one in reality, while at the same time eliminating mechanical wear and unreliable human intervention.

Due to unavoidable inaccuracies in the simulator, one encounters what is known as the "reality gap" [6], that is, a difference in performance between the simulation and the real system. Despite this problem, reasonable-quality solutions can still be found by evolution which at least qualitatively reflect the behavior predicted by simulation when they are transferred to reality. However, tuning the simulator to reduce the reality gap should do more than just make designs more transferable; we expect it will allow simulated agents to cope with and exploit otherwise inaccurately or completely unrepresented dynamics of the system, thus reshaping or opening up new territory for evolution to explore. Several interesting approaches are currently being explored for dealing with the issue of the reality gap [7, 8, 9, 10].

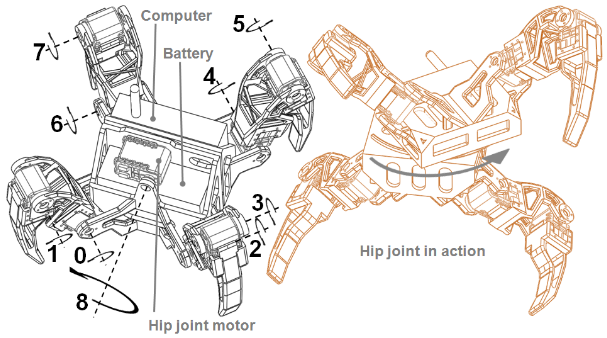

Fig. 1: Schematic view of the robot with the nine joints and associated servos labeled.

In this work, we investigate the suitability of using simulation in the evolution of locomotion in the QuadraTot quadruped robot. The robot has some unconventional characteristics, such as limited motion of the legs and a hip joint allowing the body to twist; see Fig. 1. Given this hardware, the goal of evolution is to design a control system that produces the fastest gait – i.e., the gait that results in the greatest distance covered in a fixed time period. The best controllers that come out of this process are then transferred into the real robot and compared with their simulated versions. Finally, we investigate some measures to reduce the difference between simulated and real locomotion.

2 IMPLEMENTATION

The QuadraTot robot, pictured in Figs. 1 and 2, has 9 joints: two in each leg and one at its center, each actuated by a Dynamixel AX-18A (AX-12A in the "knee" joints) servo. Fully extended, it measures 68 cm across; crouched, 34 cm. With the power supply separate from the body in order to

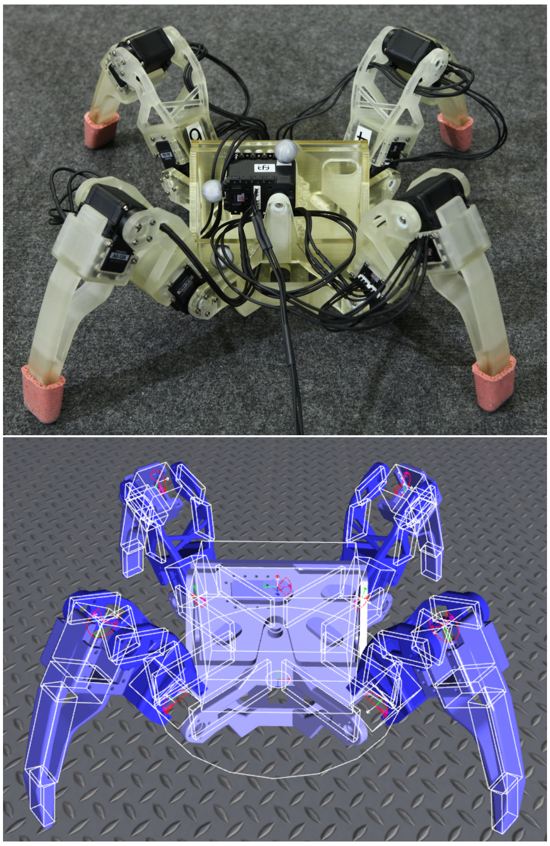

Fig. 2: The robot in reality and in simulation. Note the spherical markers for motion capture on the real robot. The white lines show the shapes for the simulation model.

minimize the strain on the relatively weak servos, the robot weighs 1.4 kg. The body parts[1] were printed on the Objet Connex 500 3D Printing System. One feature was added beyond the original design of the robot: silicone rubber "socks" were attached to its feet to improve traction.

To simulate the dynamics of the QuadraTot robot, we employed the NVIDIA PhysX physics simulation software library. PhysX provides accurate approximations of 3D rigid body motions, collision detection, and motorized joints, to name a few of the features relevant to our work. We built a model of the robot in PhysX to capture the salient aspects of its design such as the lengths of its body parts, positions and types of its joints, and the masses and rough shapes of its parts. The building blocks for the part shapes were boxes of various sizes and orientations. A detailed 3D mesh was presented using OpenGL to make visualization of the simulation more appealing and intuitive. The shapes and the overlying mesh can be seen in Fig. 2. The servos were modeled as motorized revolute joints, where the motor force was proportional to the difference between the actual and target angle; joint parameters were calibrated by observing the response of the real servos.

[1]Available online at `http://creativemachines.cornell.edu/evolved-quadruped-gaits`

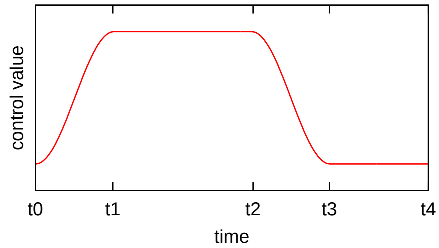

Fig. 3: The motor control function.

To control the motors in each of the robot's joints, we implemented a simple periodic control system consisting of a parameterized smoothed pulse, illustrated in Fig. 3. All controllers operate at the same frequency, but have different curve parameters, as well as individual phase shifts, ϕ. The *attack* parameter decides the time between t_0 and t_1, $pause_0$ the time between t_1 and t_2, *decay* the time between t_2 and t_3, and $pause_1$ the time between t_3 and t_4. The controller output is further parameterized by selecting the *center angle* for the pulse, as well as the *amplitude*.

Our reason for choosing such a simple system is threefold: First, the control system is not the focus of this work; second, in nature, locomotion on flat ground is observed to involve simple periodic motion; and third, the relatively small number of parameters reduces the size of search space for the genetic algorithm (GA), thus speeding up evolution.

For the evolutionary runs, we used the Simple GA method of the GALib software library. The fitness value for the experiments was calculated as the average speed of the robot during the evaluation, i.e., the total distance traveled divided by the simulated evaluation time. The joint parameters were encoded for each of the 9 joints in a binary genome with a total length of 314 bits. A population of 200 individuals was evolved for 300 generations. The bit-flip mutation probability was set to the inverse of the genome length. One point crossover was used with a probability of 0.2.

To observe the motion of the real robot, we employed an infrared camera-based NaturalPoint OptiTrack motion capture system consisting of 8 cameras. Four reflective markers were placed on the robot core to identify its motion. The position of one of these markers, sampled at 60Hz, was logged for the experimental results in the next section.

3 EXPERIMENTAL RESULTS

Where possible, we set simulator parameters to exactly known values, such as the force of gravity and the masses and dimensions of body parts. We set joint angle limits to constrain the motion to a range consistent with the physical robot: the inner joints could swing between -106°and 75°, the outer joints between -141°and 125°, and the hip joint between -53°and 53°. Joint motor forces were set to a very large value. We guessed, rather than measured, the coefficients of static and dynamic friction to both be 1.0. Finally, we chose values for the skin width (i.e., the depth to which

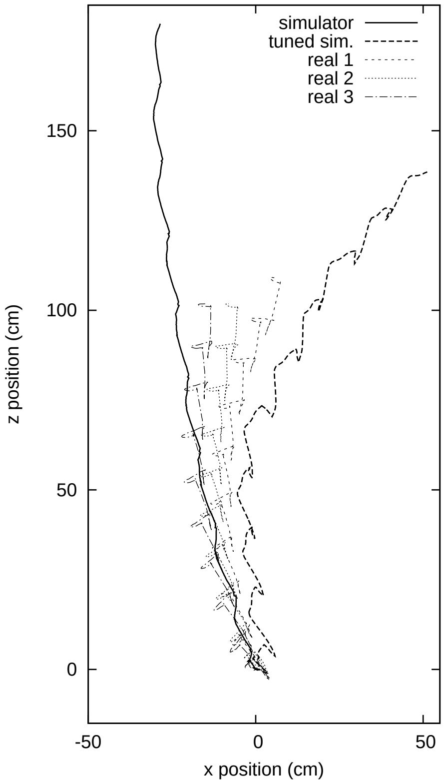

Fig. 4: Horizonal position plot, gait 1 over 10 seconds.

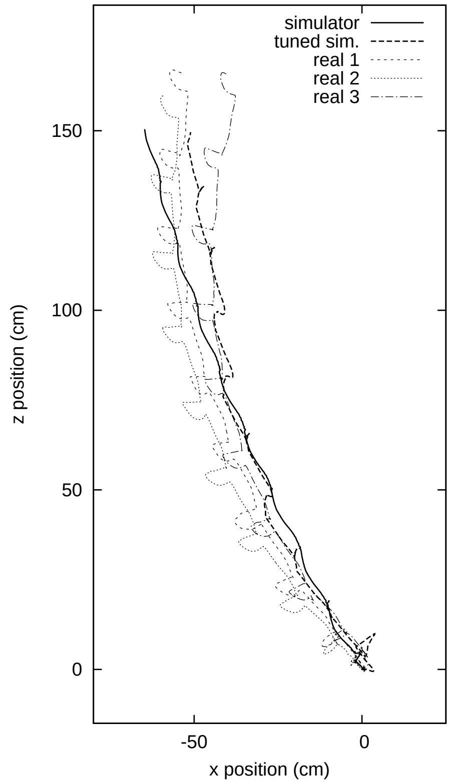

Fig. 5: Horizonal position plot, gait 2 over 10 seconds.

objects are allowed to interpenetrate before being considered to have collided), the joint constraint solver iteration count, and the simulator time step as recommended by the PhysX documentation and from prior experience to 0.05 cm, 200 iterations, and $\frac{1}{60}$ s, respectively.

With the simulator thus configured, we ran the GA to produce some gait patterns, and selected two of the fittest gaits from the final generation based on their qualitatively different strategies. The selected gaits were transferred into the real robot and their positions were recorded[2] for a period of 10 seconds. The resulting gait speeds are compared in Table 1. We then tuned the simulator as an initial attempt to reduce the reality gap for these two gaits. Both static and dynamic friction coefficients were reduced to 0.4. Also, to reproduce a perceived differential slipping tendency in the real robot's feet, anisotropic friction was added such that the feet would slip more easily from side to side (friction coefficients set to 0.1 in this direction) than front to back (friction coefficients set to 0.8 in this direction). Figs. 4 and 5 compare the real and simulated (both before and after tuning) motions for these gaits.

Table 1: Evolved gait speeds

gait	simulated	real (avg 3)
gait 1	18.3 cm/s	10.5 cm/s
gait 2	16.4 cm/s	17.8 cm/s
best in [4]	NA	9.7 cm/s

4 DISCUSSION

We observe from the experiments that the GA found promising gaits given the robot design and the imposed restrictions. The gaits shown in Figs. 4 and 5 employ two different strategies that could be similar to what a human designer might implement: the former is reminiscent of a quadruped animal; and the latter uses a worm-like locomotion strategy where two of the legs serve mostly as support. However, it appears that the solutions could be further tuned to improve performance. The parameter-based model imposed several constraints, including the amount of rotation possible in each joint, thus limiting the range of motion of the limbs. If a greater range of motion were allowed, this would result in both a larger search space and the possibility of exceeding physical limitations; however, the simulator-based approach would be more suitable for this than risking invalid combinations on the target hardware. We noticed that the core joint of the robot was not exploited noticeably in the evolved gaits. This may be due to the fact that its movement was restricted due to frequent motor overload on the real robot. A better simulation of the allowed forces could open up a path towards higher quality gaits.

The observed locomotion speeds were larger than those in found by previous online evolution experiments. Our best

[2] Gait videos: `http://folk.uio.no/kyrrehg/quad`

gait in reality achieved 17.8 cm/s, whereas highest speed found by [4] was only 9.7 cm/s. This difference could be explained by the different control systems and their parameterization or by the larger number of evaluations performed in the evolutionary search with the simulator. Additionally, it should be noted that there are some differences in the experimental setups, in particular with regard to the surface friction and the material used for coating the robot feet, as well as some differences in servo models.

As expected, we observed a difference between the simulated robot behavior and the behavior in the real robot, although it was not as large as anticipated. From the observations of the first gait, the qualitative impression of the behavior is the same, but the real robot turns faster. It seems that this is because of differences in friction between the simulator and reality, which might also account for the more jagged trajectory observed in the position plot. The reality gap observed in the second gait was smaller; although the trajectories were not identical, there was little impact on the final position. We suspect that friction played a smaller role in this gait due to the different contact motion between the legs and the surface, and the initial results from tuning the simulator support this claim. These results indicate that the simulator gives a fairly realistic model of the real robot and that additional tuning is likely to further improve the realism.

We observed during the experiments on the real robot that, after several runs, the motors seemed to lose energy, eventually shutting down with an overload error. We tried to mitigate this problem by disconnecting the power between runs. This should be addressed in future experiments by carefully tuning the model of the motor strengths in the simulator and possibly also instructing the evolution to discourage locomotion which stresses the motors too much.

5 CONCLUSION AND FUTURE WORK

We have developed a simulation environment for an unconventional robot design, where learning has previously only been performed on the real robot. This has allowed design of locomotion through a GA in which evaluations were performed in a simulator, saving time, resources, and wear associated with running EAs on real robots. The results using a simple parametric approach are better than an earlier approach using real world evolution for parametric gaits as well as HyperNEAT. A promising path of future work would be to investigate the use of more sophisticated control algorithms on the proposed evolutionary setup, for even more efficient locomotion. Some of the evolved gaits suffer from the reality gap when transferred to the real robot, whereas others perform closer to the simulated behavior. Tuning of some simulator parameters seems to be one way to improve transferral to reality. Future work should investigate various mechanisms for facilitating the transfer from simulated solutions to real ones, including more sophisticated motion capture of the robot limbs, better and more automated tuning of the simulator, as well as evolving for robustness, e.g. by introducing noise into the simulation.

ACKNOWLEDGEMENTS

The authors would like to thank Jason Yosinski for sharing experience from earlier experiments on the robot as well as providing helpful comments on the paper.

Abstract:
Developing motions for humanoid robots is a time consuming task. However, we note that sport or dance instructors can easily adjust their students' postures by simple touches. This suggests the possibility of exploiting touch for motion development, and allows us to propose a methodology based on this concept. This requires defining how the robot should interpret user's touches. We propose a supervised learning approach for coping this issue, and verify its feasibility experimentally. We then study the data collected by the algorithm, and show that the system is usable both for motion development and as a tool for studying human-robot tactile communication. In particular, considerations on the sparsity that characterize the whole process are presented, and policies for an efficient interpretation of tactile instructions are drawn.

Keywords: humanoid robot, human-robot interaction, touch, tactile communication

1 INTRODUCTION

Humanoid robots often have a high number of degrees of freedom, that makes developing motions challenging. Having robots to do automatic learning of the motion is often impossible. To compensate this, various ways of transferring human knowledge into the robot exists in literature. When the task is known in advance, the programmer may insert his knowledge in the robot's control algorithms, such as in the design of a Central Pattern Generator structure [1]. When the task is only partly known in advance, the programmer can provide modules or motion primitives, as in the Mimesis model [2], while the final user specifies the task motion by composing these elementary modules. Finally, the task may be unknown a priori and in such case the final user must be able to transfer its knowledge to the robot directly, as in Motion retargetting [3] and Kinesthetic demonstration [4].

Our proposed method, Teaching by Touching (TbT), aims to tackle the third case. The idea is to mimic the way sport or dance instructors use touch to correct their students' movements. In conventional approaches [4], robots are completely passive during the learning process. The user is required to force the posture of the robot to the desired one, by application of the necessary forces. Conversely, we propose to equip the robot with knowledge on the meaning of touch instructions, and give it an active role in interpreting the given touch for moving according to the estimated user's intention.

The main issue of such a system lies in the definition of how the touch instruction should be interpreted by the robot. Different approaches exist. The first is to force the user to learn and use a fixed protocol. In this case the robot interpretation algorithms can be very simple. It is sufficient to interpret the instructions according to the mapping. However, the user needs to remember which touch instruction brings the robot to his desired posture, and this may be difficult for inexperienced users. The other way is modeling the way human's communicate through touch. In this case the user can just intuitively provide a touch instruction and the robot will try to interpret the meaning based on all of the available information.

Our system takes the second approach, as explained in the following Section. Section 3 will present the hardware and the system we developed, which can be used both for motion development and for studying the mapping between instructions and desired robot responses. The ability of studying the mapping is important, because it allows extraction of general criteria for the interpretation of tactile instructions, that can be used for the future design of better tactile instruction interpretation algorithms. Section 4 will conclude the paper by summarizing the main results.

2 ALGORITHM

In order to build a model of the mapping between touch instructions and desired responses, data collection of how human interpret touch is necessary. Our system collects these data online, during the motion development itself. In this way no initial model is required, and the model can be progressively refined as the user interacts with the robot.

Fig.1 schematizes the data collection methodology. When the user applies a touch instruction and the robot takes a wrong interpretation, the user notifies the robot that the interpretation is wrong, and shows the correct interpretation by manually moving the robot to the pose as he expected.

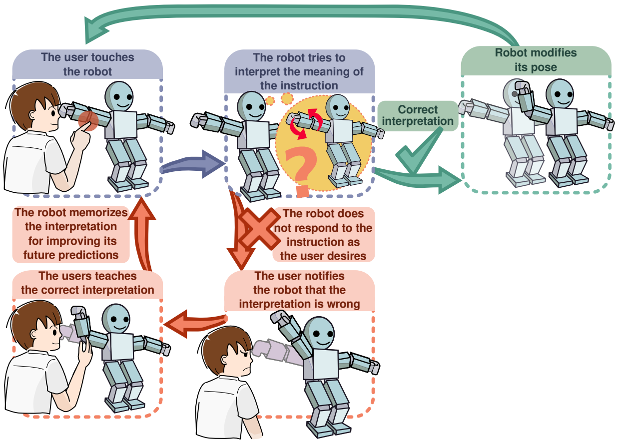

Fig. 1. Teaching by Touching motion development process.

The robot records this example of touch instruction and corresponding desired response into a database, and uses it for improving subsequent interpretations.

The database of collected data is taken as input by a Kernel regression algorithm, used for the computation of the expected meaning of the instructions received. Formally, the input $I \in \mathbb{R}^{n+m+o}$ consists of the touch sensor information $\bar{I} \in \mathbb{R}^n$, where n is the number of sensors, and the context of the robot $\check{I} \in \mathbb{R}^{m+o}$, included becaus it could influence the correct interpretation of the tactile instruction. In our implementation, the context is given by the current position of the m motors and $o = 2$ accelerometer values that represent the robot's spatial orientation. The output is a robot response, properly a rotation angle for each of the motors $M_* \in \mathbb{R}^m$.

The output of the algorithm is defined as $M_* = \sum_{i=1}^{E} \omega(I_*, I_i) M_i$ where E is the number of examples in the database, I_* is the current input from the sensors, I_i is the i-th example input, M_i is the i-th example posture change, and $\omega(I_*, I_i)$ is a kernel function, defined as

$$\omega(I_*, I_i) = \begin{cases} 0 & if\ \exists s : s \in \Psi_i \wedge s \notin \Psi_* \\ \dfrac{\prod_{s\in\Psi_i} \bar{I}_*^{(s)}/\bar{I}_i^{(s)}}{1+\sqrt{\|\check{I}_* - \check{I}_i\|_2^2 + \sum_{s:\notin\Psi_i} (\bar{I}_*^{(s)})^2}} & otherwise \end{cases} \tag{1}$$

with $\bar{I}_i^{(s)}$ denoting the input from the s-th tactile sensor and Ψ_i the set of sensors pushed in the i-th example. This kernel assures that when the sensors are pushed further the joint rotation angles are larger. Its denominator has the role of reducing the influence of the examples that present a context strongly different from the current context $\check{I}_*$. The condition on the set Ψ_* imposes to ignore all the examples relative to the pressure of touch sensors not being pressed in I_*.

The output of the algorithm M_* is used to modify the motion. In particular, the motion of the robot is defined as a set of keyframes F_k that specify the position of all the motors for a certain time t_k of the motion (positions for times $t_k < t < t_{k+1}$ are obtained by linear interpolation of F_k and F_{k+1}). After selecting a time instant t on a GUI, the users can touch the robot, and modify its posture at time t from F_t to to $F_t + M_*$ by simple touches.

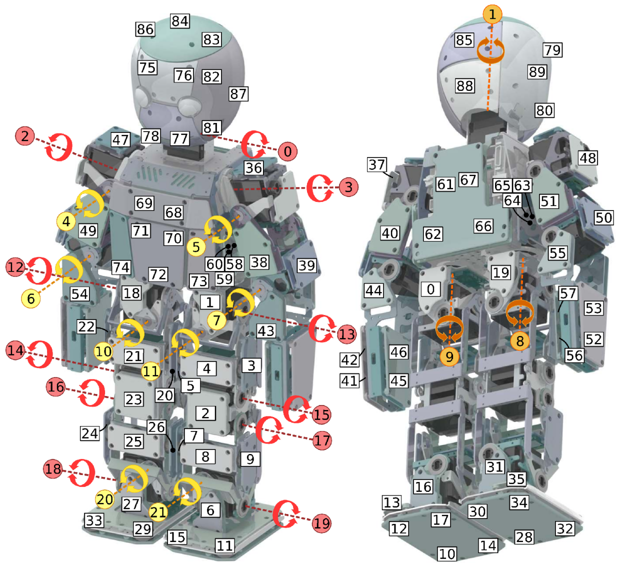

Fig. 2. Diagram of M3 Neony's motors and sensors.

3 EXPERIMENT

To verify the feasibility of the approach, we requested four people that never used the TbT system to develop a motion based on the first half of *Algorithm Exercise*, a dance from a Japanese TV show. The users had a reference motion video, but were allowed to decide when they are done developing the motion.

3.1 Hardware

The experiments were performed with a humanoid robot capable of recognizing touch, M3-Neony [5], a humanoid robot of small size equipped with a high number of tactile sensors developed as a suitable platform for tactile interaction. M3-Neony features 22 41KgF·cm servomotors, 90 tactile sensors (shown in Fig. 2), 3 accelerometers, 2 gyroscopes, 2 cameras and 2 microphones. The tactile sensors are composed of photointerruptors that translate the change of the force applied to the robot into a change in the light received by a phototransistor, as shown in Fig. 3. The experimental setup can be seen in Fig. 4. In particular, a pedal is used to notify the robot that its tactile interpretation is wrong, and allows the user to start providing the correct interpretation, that the robot stores as a (I_i, M_i) couple.

3.2 Results

All the users that attended the experiment performed the task with the proposed system without difficulties, or need for assistance, showing that the system reveals itself to be

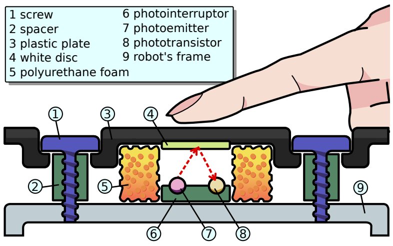

Fig. 3. Schema of tactile sensor structure of M3-Neony.

intuitive for first time users. The development time for the four users was, respectively, 221, 222, 176 and 476 minutes. Direct inspections of video recordings of the interaction show that users spent much time for robot stabilization, beyond our expectations. This confirms experimentally the importance of applying self stabilizing techniques, as the ones in [6], even for the development of quasi-static motions. Future works will introduce the concept of motion stability in the interpretation of tactile instructions, to allow the robot interpret the user's desire of making the robot balanced and let the robot compute the necessary adjustments.

One of the advantages of the systems is, as previously stated, the possibility of studying features of the way users employ touch for teaching. One of the main features that can be noticed by direct data inspection is the sparsity in the tactile interpretation taught by the users. In practice, users mainly touched few sensors and associated interpretations that involve the movement of few motors. As a more quantitative analysis, Table 1 reports the mean over the examples of the Gini index for the sensors ($G(\bar{I}_i)$) and for the motors ($G(Mi)$), $1 \leq i \leq E$.

This strong sparsity suggests us that the mapping between sensors inputs $I_i \in \mathbb{R}^n$ and motors $M_i \in \mathbb{R}^m$ could be sparse as well. To verify this hypothesis, we approximate the mapping with a linear function, and study the effect of enforcing sparsity in the mapping. More specifically, let us consider M_i, $1 \leq i \leq e$. Let us train a linear predictor $B_e \in \mathbb{R}^{m \times n+1}$ such that $M_i \approx B_e \left[\begin{array}{cc} 1 & \bar{I}_i \end{array} \right]^T$ by setting the k-th row of

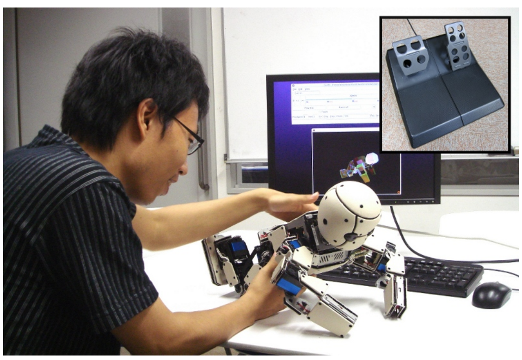

Fig. 4. Experiment environment, inset shows the pedal.

Table 1. Gini Index

	A	B	C	D
$avg_{1 \leq i \leq E} < G(\bar{I}_i)$¿	0.96	0.90	0.98	0.92
$avg_{1 \leq i \leq E} < G(Mi) >$	0.82	0.78	0.87	0.70

$B_e^{(k)}$ as $[b_e^{(k)} \beta_e^{(k)}]$, with $b_e^{(k)} \in \mathbb{R}$ and $\beta_e^{(k)} \in \mathbb{R}^n$ minimizers for the cost function

$$\frac{1}{2N} \sum_{i=1}^{e} \left(M_i^{(k)} - b_e^{(k)} - \beta_e^{(k)} \bar{I}_i \right)^2 + \lambda \left[(1-\alpha) \frac{1}{2} \|\beta_e^k\|_2^2 + \alpha \|\beta_e^k\|_1^2 \right] \quad (2)$$

where $M_i^{(k)}$ is the rotation for the k-th motor in M_i, $\|.\|_2$ denotes the Euclidean norm, $\|.\|_1$ the ℓ_1 norm, $\alpha, \lambda \in \mathbb{R}$ are constants. We note that, as $\alpha \to 0$ the minimization resembles classic linear regression and as $\alpha \to 1$ the minimization favors sparsity [7]. Let us test the generalization capabilities of the predictor by computing the error on the $e+1$-th couple $(\bar{I}_{e+1}, M_{e+1})$, that is, compute the error

$$\varepsilon_e = \left\| M_{e+1} - B_e \left[\begin{array}{c} 1 \\ \bar{I}_{e+1} \end{array} \right] \right\|_2 \quad (3)$$

for different values of α. The average error over $2 \leq e \leq E$ is reported in Fig. 5. The graph clearly shows that increasing the sparsity of the predictor improves the performances, providing support to our hypothesis of strong sparsity in the mapping as well. Previous works [8] showed that the desired responses M_i lie in a subspace of the whole motor subspace, analogously to the tendency for motions of lying in small subspaces of the whole command space [9]. We also found that the two spaces are strongly correlated, i.e. that if we know the frames F_k, $1 \leq k \leq K$ of the motion being developed we can compute the subspace $span < F_1, \ldots F_K > \subsetneq \mathbb{R}^m$ where the M_i have high probability of being located. Motivated by the previous results, we can verify whether also in this case sparsity can improve our predictions. In detail, let us define the matrix

$$\Gamma_{e+1} = \left[\begin{array}{ccc} 1 & \ldots & 1 \\ F_1 & \ldots & F_{K'} \end{array} \right] \quad (4)$$

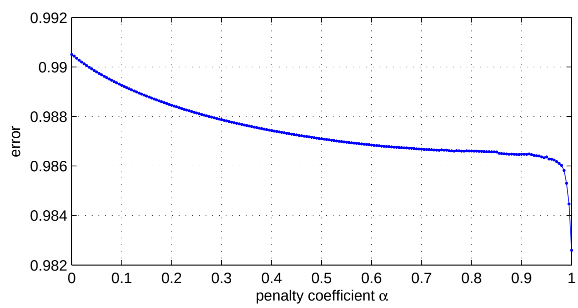

Fig. 5. Average error ε_e for the four users for different values of α.

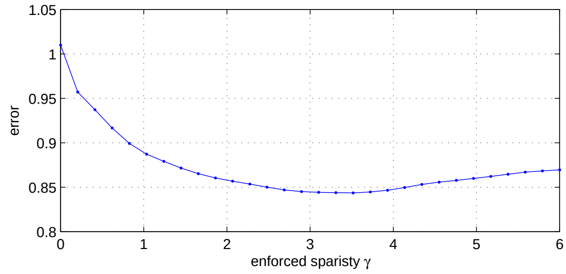

Fig. 6. Average error δ_e for the four users for different values of γ.

of the frames available before the couple $(\bar{I}_{e+1}, M_{e+1})$ is taught. Let us compute B_e and the prediction $p_{e+1} = B_e \left[\begin{array}{cc} 1 & \bar{I}_{e+1} \end{array} \right]^T$ as above, and define ρ_{e+1} as the minimizer of $p_{e+1} - \|\Gamma_{e+1}\rho_{e+1}\|_2^2 + \gamma\|\rho_{e+1}\|_1$. This new value $\rho_{e+1} \in \mathbb{R}^{m+1}$ is essentially a projection on Γ_{e+1} of the prediction p_{e+1}, whose sparsity is enforced increasing γ. Again, we compute the average error

$$\delta_e = \left\| M_{e+1} - \Gamma_{e+1} \left[\begin{array}{c} 1 \\ \bar{I}_{e+1} \end{array} \right] \right\|_2 \tag{5}$$

over the examples, and report the results in Fig. 6. We notice that the best predictions are obtained for $\gamma > 0$, confirming that also in this case sparsity of the projection coefficients can improve our estimates.

4 CONCLUSIONS AND FUTURE WORK

In this paper, we presented a system that allows to teach whole body motions to humanoid robots by physical interaction. Conceptual aspects of the exploitation of touch for motion development were briefly discussed, and a practical system implementation, comprising a small-sized robot equipped with 90 tactile sensors over the whole body was briefly introduced. This system has a two-fold role. On the one side, it allows inexperienced users to develop robot motions. On the other side, it allows studying the way users employ touch to intuitively communicate with robots.

As an example of the possible analysis that can be done on tactile instructions, this paper reports a study on the importance of sparsity in the mapping between pressed sensors and desired robot movements. First, quantitative measures on the sparsity of the input signal (touch sensors pressed) and the output signals (motors that should be moved) were reported. Successively, the possibility of improving the mapping from tactile instructions to motor movements by imposing sparsity was investigated. Finally, the idea of using the frames of the motion itself to improve the prediction on the robot movement was studied. In particular, it was shown that if we restrict the choice to a small subset of them (again, by imposing sparsity in a coefficient vector), then the prediction on the robot movement desired by the user can be improved.

This analysis provides us with important criteria for the design of new algorithms for tactile interpretation. In particular, it tells us that ensuring sparsity can give great performance improvements. For instance, if a neural network is employed for mapping tactile instructions to robot responses, then using rectifying neurons [10], that assure sparsity, appears to be a good choice. Future works will deal with the extension of the analysis reported here and the design of better, more performing algorithms for tactile interpretation based on this analysis.

An intelligent human behavior based automatic accessing control system

ChinLun Lai

Oriental Institute of Technology, Taipei, Taiwan, R.O.C.

fo001@mail.oit.edu.tw

Abstract: In this paper, an innovative intelligent controlling system for automatic door accessing is proposed to improve the drawback of frequent false actions among the existing control systems, while increasing the added values for extra security applications. Through pattern recognition techniques, the proposed system can precisely identify those people with intention of entering and/or leaving the door, and then control opening and closing of this door as a response. The experimental results indicate that our system has the advantages such as high precision, high reliability, and controllability in response to demands. In addition, the product prototype also has the economic benefits of low costs, high added-value, etc. Thus, it is a highly competitive new product.

Keywords: automatic door controlling, behavior analysis, human detection, pattern recognition

1 INTRODUCTION

Automatic door control is convenient and is widely used in many public places such as shores, businesses, transportation stations, airports, and wholesale department stores to eliminate the need of manually opening and closing the doors. However, there exists severe drawback in the existing approaches, ex: they are unable to determine the type and the intention of the detected object. In other words, a puppy or a bicycle passing by will trigger an action to open the door. In addition, even with the help of other technologies they may verify that the object is a person, they are still unable to indentify the intention of the person. For instance, a pedestrian or a person stays close to the door chatting might still trigger the door opening/closing. Frequent false actions not only wastes control and air conditioning energy, but also reduces equipment life time. This calls for the needs of an automatic door control system based on image recognition and intention analysis.

In the proposed method, the action of the door is based on the confirmation that the object is a human body, and movement trajectory indicates his/her intention to access the door. In our approach, an anti-pinch measure has been added to eliminate the false actions among existing systems. We detect the existence of human face other than the human geometric shaped (head, torso) scheme since it is well developed with reasonable detection rate and has the closest resemblance to real human characteristics. In addition, the images can also be saved for latter analysis for the applications such as crime investigation and prevention.

This paper is organized as follows: Section 2 describes the system design concept and related theoretical basis, while the corresponding hardware implementation architecture is described in section 3. Section 4 states the results and the analysis of various field tests of the system prototype, followed by discussions. Finally, the conclusion and future work are made in the last part.

2 THEORETICAL BASIS

2.1 Human face detection

The related researches on human face detection in the past ten years can be classifies into two types: the detection method based on skin color characteristics [1] and the detection method based on the training of human face database [2-4]. The former considers the blocks with the known skin color characteristics in the images as candidate blocks, and then the existence of isosceles triangles formed by eyes and mouth within the blocks can be used to confirm human faces. In the latter method, neural networks [2] or Adaboost [3-4] training methods are used to find human facial features and detect human faces in the established facial image database. The proposed system will use the Adaboost human face detection method to determine the existence of human object.

2.2 Analysis of the object moving trajectory

To determine whether the human object in the monitored areas has the intention to enter the door, the cumulative density function (*CDF*) obtained from tracking the trajectory of the human face movement is used to determine if the person has the intention to enter the door. Thus, this section will be divided into two parts: the tracking of human faces and the estimation of probability distribution of movement trajectory. In the first part, the tracking of human face is realized by comparing if the overlapping area of human face between time t and $t-1$ is smaller than the threshold value. In the second part, the human face moving trajectory of the person with the intention of entering will be estimated to figure probability distribution of x and y axis. Then this probability distribution will be used to establish the probability matrices of the monitored areas to estimate the probability values corresponding to different positions. Finally, this probability value will be used to calculate the cumulative density function corresponding to the movement of each human face to determine whether or not the intention of entering exists.

If a pedestrian within the monitored region (*MR*) has the intention of entering a specific region, there should be characteristics of continuous movement trajectory toward the specific exit/entrance, or looking at the specific exit/entrance with greater time accumulation, etc. Therefore, through the movement trajectory and the spatial position the pedestrians within the monitored regions, in this research the temporal and spatial cumulative probability is calculated and used to determine the intention of entering a specific region. As to the movement trajectories, those pedestrians with the intention of entering the specific region shall gradually move toward the entrance in the process. As to the spatial positions, the position closer to the entrance should be with the higher probability of intention to enter. On the contrary, the position farther to the entrance should be with the lower probability. According to the above description, the probability values of human faces based on their spatial positions within the monitored region is estimated, and then to obtain the cumulative probability in time-space to confirm whether the person has the intention of entering the specific region based on the movement trajectories of the human faces in time.

Since it cannot be predicated from where the pedestrian will enter, in order to obtain the probability of the human face in various positions in space in this research, we assume the center position (x_c^t, y_c^t) of a human face as a random variable. Thus, the movement trajectory of its center point shall have a specific probability distribution during the movement process. First we preset the movement trajectory of the pedestrian from entering the monitored region gradually moving toward the specific exit/entrance, and then according to different starting positions they can be divided into six kinds of entering conditions: upper left, upper right, right above, left, right and lower shift as shown in Fig. 2(a). Then the one-dimensional histograms for x and y and their respective probability distributions can be obtained through vertical and horizontal projection in space, such that the probability value of the human face at various position points within the monitored region can be obtained.

In order to obtain the spatial distribution of the movement trajectories, 20 sets of real movement trajectories data for each different entering condition is calculated, so there are a total of 120 sets of trajectories. Assuming the movement mode of each set is a_i, i=1,…,120, accumulate the 120 sets of movement mode into the statistical image $s = \sum_{i=1}^{120} a_i$. Then the spatial distribution characteristics of movement trajectory can be obtained as shown in Fig. 2(a). Then, the statistical images is projected onto the *x*-axis and *y*-axis in space to obtain the one-dimensional histograms of the vertical and the horizontal spatial characteristics of the movement trajectory, as shown in the blue lines in Fig. 2(b) and 2(c).

Since the one-dimensional histograms generated from the projections of *x*-axis and *y*-axis are the spatial distributions of movement trajectories in the *x*-axis and *y*-axis, this paper uses the estimation method of probability density function (*pdf*) of histogram and the nonlinear least squares curve fitting [5-6] method to estimate the *pdf* of spatial distribution of movement trajectories in the *x*-axis and the *y*-axis respectively. As shown in the experimental results, the probability density function of vertical projection approximates to Gaussian distribution with the average value μ and standard deviation σ as 150 and 1 respectively as shown in (1a). The probability density function of horizontal projection approximates to non-central chi-square distribution with the degree of freedom k as 2 and the non-centrality λ as 23 as shown in (1b).

$$s_v(x) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{(-(x-\mu)/2\sigma^2)} \tag{1a}$$

$$s_h(x;k,\lambda) = \frac{1}{2} e^{-(x+\lambda)/2} (\frac{x}{\lambda})^{k/4-1/2} I_{k/2-1}(\sqrt{\lambda x}) \tag{1b}$$

where the probability distribution functions of (1a) and (1b) are shown in red dotted lines in Fig. 2(b) and (c).

Through the inclusion-exclusion principle [7] of the probability theory, the probability value of human face at each spatial position point is calculated as in (2).

$$p(x_c, y_c) = s_h(x_c) + s_v(y_c) - s_h(x_c) \times s_v(y_c) \tag{2}$$

where $s_h(x_c)$ and $s_v(x_c)$ are the probability values corresponding to the center coordinates of the human face. From (2) the probability matrix (*PM*) of each position point within the monitored region can be obtained. The probability matrix also represents the counter weight values of the various coordinate positions within the monitored space. From the variation of the probability value of the probability matrix, it is observed that the corresponding probability value is larger for position closer to the specific entrance. On the contrary, the corresponding probability value is smaller for position farther away from the specific entrance as shown in Fig. 2(d). Higher gray scale values represent higher probability values.

In order to detect whether or not the movement trajectory of the pedestrian is getting closer to the specific exit/entrance, it is assumed that a pedestrian with the intention of entering will go through τ images after entering the monitored area before getting to the entrance, and the movement trajectory probability of the human face center point of the person should be $p(x_c^i, y_c^i),\ i=1,\ldots,\tau$. Thus, the cumulative distribution function (*cdf*) [7] up to the τ-th image is described as:

$$p_{enter} = \frac{1}{\tau}\sum_{i=1}^{\tau} p(x_c^i, y_c^i) \tag{3}$$

The cumulative probability of the pedestrian up to the τ th image can be obtained by (3). If the pedestrian continues to move toward the exit/entrance gradually or continue to look at the entrance, then the cumulative probability value P_{enter} will exceed the threshold value TH_{PM}, then the intention to enter the specific region can be determined. On the contrary, if this value is smaller than the threshold value, then it's determined that the person does not have the intention to enter, and this case will be excluded. Since the intention of accessing the specific exit/entrance should be greater for the person closer to the exit/entrance, in this research we assume the region with greater than average value μ_{PM} the probability matrix as the main monitored region (*MMR*), and this average value of the probability matrix μ_{PM} will be used as the cumulative threshold value

TH_{PM} to determine if the intention of entering exists. Thus, when the pedestrian is walking toward the specific exit/entrance location gradually, the movement trajectory of the person will fall mostly in the *MMR* (as indicated in the area enclosed by red area in Fig. 2(d)), and the cumulative probability value will become higher along with the accumulation of time and with the center point of human face center approaching the specific exit/entrance. Once it exceeds the threshold value, it's determined that the intention to enter exists and the door will be opened accordingly. Otherwise, it would be determined that the intention to enter did not exist. When the pedestrian continuously looks at the exit/entry within the *MMR*, P_{enter} will exceed the threshold value along with the accumulation of time. Thus, it can also be determined that the intention of entering the specific region exists.

To avoid the pedestrians from being pinched by the closing door before entering/leaving a specific exit/entrance, a modified temporal difference method [8] is adopted to determine whether or not there are moving objects near the exit/entrance, and the determination of whether or not the pedestrian has entered/left the specific region will be used as the basis for activating the door closing procedure.

To confirm whether the pedestrian has entered/left the specific exit/entrance, 1/3 imaging area in front of the exit/entrance is preset to be the anti-pinch monitoring region (*AMG*). The temporal difference method will be used to detect the existence of any foreground within the monitoring region as the basis for activating the door closing procedure.

Temporal difference is to detect the pixel different from the previous moment *t-1* by subtracting two adjacent images in the same image sequence. When this pixel is greater than the threshold value ε, it will be determined as foreground pixel by

$$Fg_i(t) = \begin{cases} 1, & |Fr_i(t) - Fr_i(t-1) > \varepsilon| \\ 0 & , \ otherwise \end{cases} \tag{4}$$

where $Fg_i(t)$ is the foreground pixel at time *t*. $Fr_i(t)$, $Fr_i(t-1)$ are the gray scale values of position *i* in the anti-pinch monitoring region at time *t* and *t-1* respectively.

Assuming the gray scale values of images are of Gaussian distribution, we use twice the standard gray scale value $2\sigma_{t-1}^{AMG}$ of the $Fr_i(t-1)$ anti-pinch monitoring region as the threshold value ε [9] for foreground detection. In order to prevent the pedestrian from repeated entering/leaving of the specific region after entering/leaving the anti-pinch monitoring region, the door closing procedure will be activated with 2-second delay if there is no foreground detected within the anti-pinch monitoring region.

The completed function blocks of the proposed system is presented in Fig. 1.

2.3 Evaluation of system effectiveness

To evaluate the reliability of the system, the total false action probability $ER_{tot}=FRR+FAR$ is defined, while *FAR* is false acceptance rate and *FRR* is false rejection rate. They can be analyzed as follows:

Since the face detection execution speed of this system is 15 frame/second, the human face detection rate (*DR*) is 0.9, the missing rate is *DF=1-DR*. The generally acceptable door opening/closing response time *T* is 2~3 seconds. It can be derived from the above description that the probability of rejection for a pedestrian who wants to enter the door is

$$FRR = \sum_{i=FF}^{TF} C_i^{TF} P(\theta, DF)^i \times [1 - P(\theta, DF)]^{TF-i} \tag{5}$$

where $TF=(Rt*T)$ represents the number of images collected within a specified time period, $FF=(Rt*T)\mu_{PM}$ represents the minimum number of times the human face must be detected, and $P(\theta,DF)$ represents the probability of missed detection of human face within the *MMR*. Under the assumption that *q* and *DF* are independent, the formula can be simplified as

$$P(\theta, DF) = P(\theta) \times DF \tag{6a}$$

$$P(\theta) = \frac{MMR}{MR} \tag{6b}$$

where $P(\theta)$ is area ratio of *MMR* within the monitored area. According to (5), if we preset the door opening response time to be 2 seconds (starting from the detection of the first face with certain distance away from the door), then the *FRR* value should be about 2.193×10^{-6}. If the door response time was set to 3 seconds, the *FRR* value would be less than 6.808×10^{-10}. Generally speaking, it takes about 2~3 seconds for a human body to move from somewhere in front of the door to the entrance to wait for the door to open. Therefore, generally the theoretical false rejection rate should be less than 2 in a million.

On the other hand, it is either the false identifications of facial characteristics (non-human face falsely identified human face) do not possess features of continuous trajectories (random occurrence), or maybe the user only passed by in front of the door. Under these two circumstances the trajectories will be removed during the tracking procedure. That is, there will be no follow-up determination of whether or not the door shall be opened/closed for that target. Therefore, *FAR* can be considered to be 0, and the total false action rate is described by $ER_{tot}=FRR$.

It is observed from the above description that false action rate of this system can be controlled within 2 in a million. Compared with the existing systems (only assuming 1/5 of the *FAR* false action rate), this system has an excellent identification accuracy rate.

3 EXPERIMENTAL RESULT & DISCUSSION

To evaluate the proposed system, A *DM365* platform of *TI*-corp. is selected to implement all the functions. The algorithms developed were programmed in *C* language and were executed under the Linux OS core. The related parameters of the prototype system are as follows: The face detection rate is 0.9. The processing speed is 15 frame/sec. The setup height is 2.2 meters. The angle of depression is 30 degrees. The left and right viewing angles of the image are both 63 degrees. Field tests were conducted in three different locations. The content of related data is presented in table 1.

The experimental results from actual field tests are shown in table 1. Among the experiments of 125 trials in 3 different locations, the number of effective opening, within the default 2 seconds value, was 124. The false rejection rate was 0.008, slightly higher than the theoretically estimated value. In the only case of failure, it was not that the door did not open, just the opening was delayed (the reaction/response time was 4 seconds). Thus, there was actually zero case when a person wanted to enter but was rejected. On the other hand, the number of false acceptance rate due to objects passing by or environmental interference was zero. It is observed that the system effectively overcomes the disadvantage of susceptibility to environmental interference among existing automatic door control systems while retaining the advantages of opening the door effectively and safely.

4 CONCLUSIONS

In this paper, an automatic control system based on the characteristics of human behavior is proposed to replace the existing automatic door control devices. Through image analysis technologies, it is capable of opening the automatic control door after accurate identification of human object with the intention to enter/exit. This way it achieves the goals of added values such as reduction of energy consumption, improved readiness rate of the equipment, and saving of the images of people who entered/exited for future references of other applications. The results of the initial field tests revealed that the developed prototype effectively accomplished the product design specification. It is truly a feasible business product.

Abstract: We here present a method for measuring human physical activity, which is based on detecting the electrostatic induction current generated by the walking motion under non-contact and non-attached conditions. A theoretical model for the electrostatic induction current generated because of a change in the electric potential of the human body is also proposed. By comparing the obtained electrostatic induction current with the theoretical model, it becomes obvious that this model effectively explains the behavior of the waveform of the electrostatic induction current. The normal walking motions of daily living are recorded using a portable sensor measurement located in an ordinary house. The obtained results show that detailed information regarding physical activity such as a walking cycle can be estimated using our proposed technique. This suggests that the proposed technique, which is based on the detection of the walking signal, can be successfully applied to the estimation of human physical activity.

Keywords: motion detection, electric potential of human body, electrostatic induction current.

1 INTRODUCTION

Physical activity improves health and well-being. The benefits of physical activity for the prevention of cardiovascular disease, cerebral accidents, and some cancers are now well established. These benefits are also enjoyed in old age, where the incidence of many diseases and disabilities increases. Researchers have made numerous attempts to develop methods to measure physical activity. This is because precise measurements of physical activity would allow assessment of physical activity in the same way as a physical activity diary. Estimates of physical activity are often made using self-report measures. However, these have some disadvantages such as the impossibility of estimating activity patterns throughout the day (Davis [1]) and fluctuations in health status (Riki [2]). Therefore, objective measurement methods for physical activity are attracting a great deal of attention as they would overcome the limitations of self-report measures. In particular, measurement of the acceleration of a subject's body provides information on the amount, frequency, and duration of physical activity (Plasqui [3]). An objective physical activity measurement method such as accelerometry can also assess free-living activity. Objective physical activity measurements (Matthews et al [4]) make it obvious that participation in non-exercise physical activity such as housework and stair climbing improves mortality risk.

In particular, it has been noted that walking for exercise is especially effective for long-term weight loss (Ballor [5]), increasing HDL (Fogelholm et al [6]), reducing blood pressure (Dunn et al [7]), and lowering the risk of heart disease and cancer initiation. In the last decade, human walking analysis has attracted much attention from computer vision researchers motivated by its wide application potential. Normally, in vision-based human walking detection, motion features are extracted from image sequences. Subsequently, feature amounts are compared as an identification process. However, in conventional human walking detection methods, experimental conditions such as the distance between the subject and camera, the angle of the camera, and the pixel density of the camera significantly influence the recognition rate of the system. Moreover, the main drawback of these methods is that they cannot detect anything in the dead zone of the camera. Furthermore, many image-processing systems require complex logic to ignore the disturbances caused by the motion of objects other than humans.

Alternatively, body-mounted accelerometers are extensively used for monitoring human motion because these systems are inexpensive compared to an optoelectronic motion capture system. Another advantage of body-mounted accelerometers is that the system is available in an indoor-outdoor space. Additionally, several methods have been presented to measure human activity using various techniques, e.g., an ultrasonic motion analysis system to temporally and spatially measure the amount of human activity, an electromagnetic 3D orientation estimation system that uses the earth's magnetic field, and a wearable ultrasonic motion analysis system. However, in these measurement systems, it is necessary to use some kind of sensor or marker that remains in contact with the subject. Therefore, these methods have not been applied to non-contact detection for human activity measurement.

In this paper, we present a new direction for a human activity estimation technique that does not use a camera or accelerometry. We have developed an effective non-contact technique for the detection of human walking motion using human-generated body charge. This technique involves the detection of an electrostatic induction current on the order of approximately sub-picoamperes flowing through an electrode placed at a distance of 3 m from a subject. The absolute value of the electrostatic induction current depends on the type of footwear and floor material. However, we confirmed that this technique has sufficient sensitivity to detect the electrostatic induction current generated by the walking motion in daily life. This technique effectively explains the behavior of the waveform of the electrostatic induction current flowing through a given measurement electrode using a capacitance model for the human body.

2 PRINCIPLE

The human body is electrically charged during walking (Ficker [8]). In the case of a subject that is standing or walking, we assume that there are two highly resistive layers between the feet of the subject and the floor, as shown in Fig. 1. One layer is the sole of the subject's footwear. The other is the surface of the floor. Capacitance C_{sf} of the feet relative to the ground may be calculated as the sum of capacitance C_s of the sole and capacitance C_f of the floor surface. In addition, C_0 is the capacitance of the rest of the subject's body relative to nearby objects on the floor. Therefore, potential U_B of the human body during walking motion can be expressed as follows:

$$U_B = Q_B \frac{\varepsilon_a S + x C_B}{C_B \varepsilon_a S}. \quad (1)$$

where

$$C_B = C_0 + C_{sf} = C_0 + \frac{C_s C_f}{C_s + C_f}. \quad (2)$$

Q_B is the instantaneous charge of the human body during walking motion, ε_a is the permittivity of the air gap between the sole and floor, and S is the effective sole area at height x above the floor. The induced charge, Q, of a measu rement electrode placed at a certain distance from the subje ct can be expressed as follows:

$$Q = C(U_B - V), \quad (3)$$

where C is the capacitance between the human body and m easurement electrode, and V is the potential of the measure ment electrode. From the above two equations, the induced current, I, flowing through the measurement electrode can b e expressed as follows:

$$I = \frac{dQ}{dt} = C\frac{dU_B}{dt} = CQ_B\left(-\frac{x}{\varepsilon_a S^2}\frac{dS}{dt} + \frac{1}{\varepsilon_a S}\frac{dx}{dt}\right). \quad (4)$$

We assume that the human body is a good conductor. The first term in (4) represents the current induced by the motion of the foot before it is lifted off the floor. The second term represents the current induced by the motion of the foot and leg after the foot is lifted off the floor. The second term is approximately proportional to the velocity of the foot. Therefore, in the case of walking motion near the measurement electrode, it is possible to measure the current generated under perfect non-contact conditions.

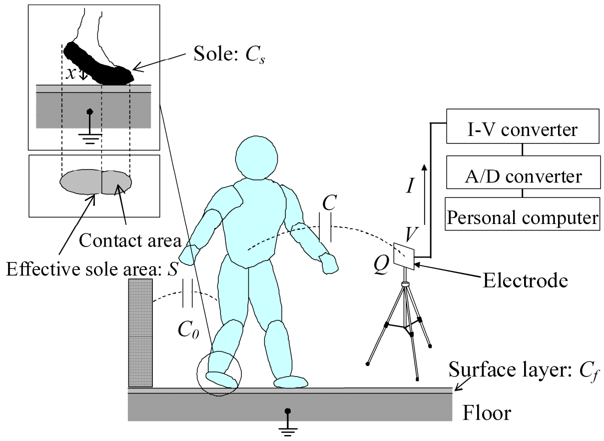

Fig. 1. Schematic of measurement system for detecting walking motion

3 EXPERIMENTAL SYSTEM

A schematic of the measurement system for detecting the electrostatic induction current generated by the changes in the electric potential of a subject's body is shown in Fig. 2. The electrostatic induction current flowing through an electrode placed less than 3 m from the subject's body is converted into voltage using an *I-V* converter with a conversion ratio of 10 V/pA and comprising an operational amplifier (op-amp). The *I–V* converter consists of two low-input-current op-amps, where C_f is 1 pF and R_f is 3 TΩ. The selected low-noise op-amp has an input offset voltage of 40 μV and input offset current of 1 pA. The feedback resistor connected to the op-amp is a hermetically sealed high register that can prevent stray current due to humidity. For such measurements with high input resistance, a conventional guarding method is absolutely imperative for shielding used with op-amps; this prevents stray currents from entering sensitive nodes. Sensitive nodes are completely surrounded by a guard conductor that is kept at the same electric potential as the sensitive node. In addition, induction currents generated by commercial power sources manifest in the form of noise. Therefore, a filtering system with a cutoff frequency of 20 Hz is used. This measurement system is unaffected by the noise from other electronic devices such as mobile phones or microwave ovens. The analog signals are subsequently converted into digital signals using an analog-to-digital (A/D) converter.

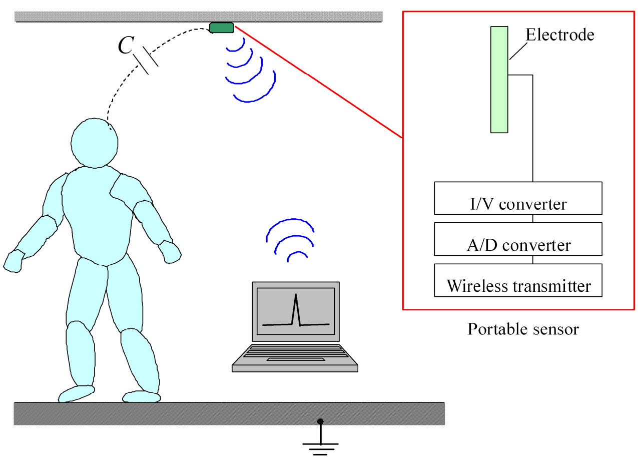

Fig. 2. Schematic of system for detecting walking motion in house by using portable sensor

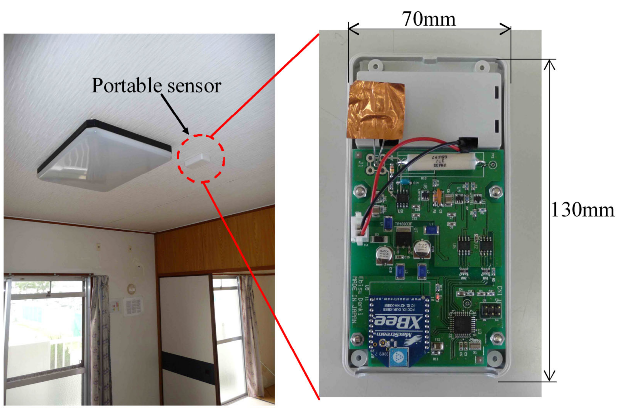

Fig. 3. Photograph of portable sensor

The analog signals are subsequently converted into digital signals using an A/D converter. We used the ZigBee protocol for wireless data transmission to a personal computer from the portable contact detection system. Data were acquired at a sampling frequency of 20 Hz, which is safe given that the actual data transmission rate on ZigBee networks is as low as about 10 kbps. However, this sampling frequency was sufficient for detecting contact events. The measurement electrode is square with a side length of 2 cm. A photograph of the portable detection sensor is shown in Fig. 3.

4 RESULTS AND DISCUSSION

Figure 4 shows the typical waveform of the current generated by the human motion of walking. Cadence components are observed in the resulting waveform for each case. These components indicate the presence of a gait cycle in the walking motion. This gait cycle consists of a combination of alternating swing and stance phases for the left and right feet. The waveform contains cadence component for both feet during bipedal walking; this reveals that the toe of the left foot is lifted off the floor while the heel of the right foot simultaneously comes into contact with the floor. When the toe of the right foot is lifted off the floor, the effective sole area, S, decreases and the distance, x, between the right foot and floor increases continuously. As a result of the walking motion, the current, I, flowing through the measurement electrode increases, as predicted by the first term on the right-hand side of (4). In rapid succession, I decreases, as predicted by the second term on the right-hand side of (4). Furthermore, in the second half of the swing phase, a rapid decrease in x induces a decrease in I, as predicted by the second term on the right-hand side of (4). In rapid succession, I decreases, with an increase in the effective sole area, S, resulting from the heel contact, as predicted by the first term on the right-hand side of (4). Therefore, (4) effectively explains the behavior of the waveform of the electrostatic induction current, I, flowing through the measurement electrode.

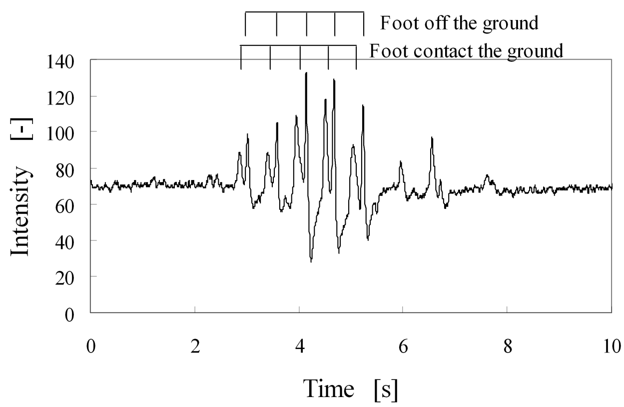

Fig. 4. Typical waveform of current generated by human walking motion

The portable sensor was placed in ceiling of an ordinary house with a wooden floor, as shown in Fig. 3. The subjects were asked to walk normally wearing slippers on a wooden floor. The waveforms of the electrostatic induction currents generated by walking motion are shown in Fig. 5. The change in the intensity of the walking signal obtained by the portable sensor suggests that the subject is drawing closer to the portable sensor and then moving away from it. Therefore, detailed information about physical activity can be estimated using our proposed technique. We have developed an effective non-contact technique for the detection of human physical activity using human-generated body charge.

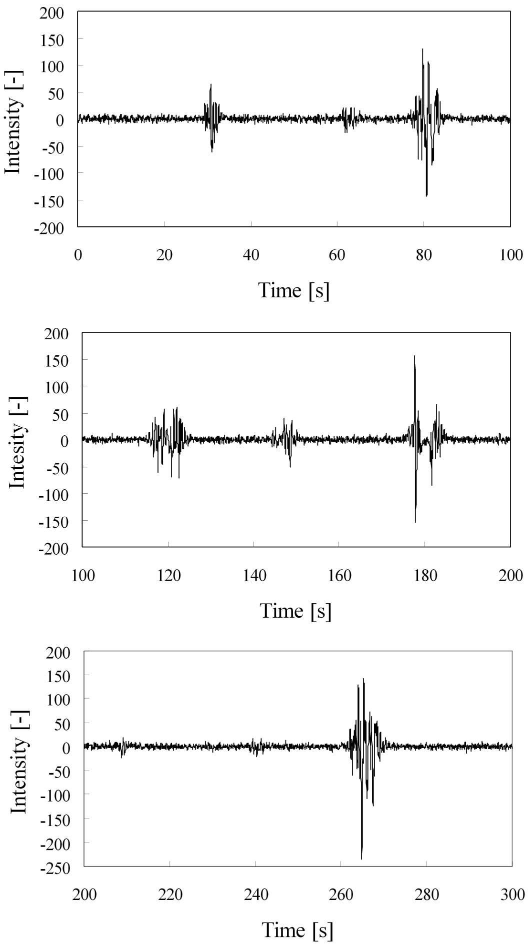

Fig. 5. Waveform of current generated by human walking motion

5 CONCLUSION

This paper described the development of an effective non-contact technique for the detection of human physical activity using human-generated body charge. This technique involves the detection of an electrostatic induction current on the order of approximately sub-picoamperes flowing through an electrode.

We proposed a theoretical model for the electrostatic induction current generated by the walking motion. By comparing the typical waveform of the electrostatic induction current obtained by walking motion with the theoretical model, it became obvious that this model effectively explains the behavior of the waveform of the electrostatic induction current, *I*, flowing through the measurement electrode. The normal walking motions of daily living were obtained using a portable sensor located in an ordinary house. The obtained results showed that detailed information regarding physical activity such as a walking cycle could be estimated using our proposed technique. Therefore, the proposed technique based on the detection of the walking signal can be successfully applied, not only to estimate human physical activity, but also to confirm the safety of an elderly person living alone.

Abstract: The travelling salesman problem (TSP) is a classic optimization whose goal is to find a shortest route path. In this paper, an improved GA is proposed to solving TSP. For eliminating repeated chromosomes and increasing their diversity, a normalization strategy is proposed. Further, for improving solution searching efficiency, the cross paths detection is also proposed to reduce paths distance. Experiments were conducted on 10 instances of TSPLIB. The results showed that the proposed method exhibits better performance when solving these TSP instances compared to related TSP approaches.

Keywords: cross path detection, genetic algorithm, optimization, traveling salesman problem.

1 INTRODUCTION

The travelling salesman problem (TSP) is a classical NP- hard problem in the field of computer science. In TSP, a set of cities' location will be given and the goal of the problem is try to find a shortest route for visit each city only once.

TSP is used as a benchmark for testing performance of optimization methods. Although there are so many contribution in enhance solution searching ability. Some of them might already be surpassed by novel approaches. In 2007, Shi et al. proposed a particle swarm optimization (PSO) based approach called Discrete PSO [1] for solving TSP. In 2008, Kaur and Murugappan proposed a hybrid genetic algorithm [2]. It combine the nearest neighbor algorithm (NNA) and pure genetic algorithm (GA) for deriving better solutions.

In order to improving optimizer's searching ability and efficiency, this paper presents improved GA to solving TSP. The proposed method is incorporated with the cross path detection to verify and eliminate redundant path for minimizing route solution. The proposed method also involved a normalization strategy to increase diversity of population, which can prevent the solutions from falling into the local optimum and enhance the proposed approach's searching ability.

2 GENETIC ALGORITHM

The basic principles of genetic algorithm (GA) were first introduced by John Holland in 1975[3]. Holland's GA was the first evolutionary computation (EC) paradigm developed and applied. It is for moving from one population of *chromosomes* to a new population by using a kind of Darwin's "natural selection" principle together with the genetics- inspired operators of selection, cross-over, mutation, and inversion [4]. A brief introduction of genetic algorithm will be described.

3 PROPOSED METHOD

Although there are numerous approaches can be applied for solving TSP. Efficiency and robustness of algorithms are still the major issues. In this paper, the nearest neighbor algorithm (NNA) is adopted for initial population. In order to reduce route distance efficiently; the cross paths detection is introduced. Further, the normalization is also involved to keep diversity of population.

3.1 Cross-over

In general, cross-over operation in GA is to generate new offspring. It combines two chromosomes' information which was also generated by chromosomes in a previous generation and evaluated by the cost function. Finally, the better chromosomes will be kept is the population. If a chromosome discovers a new probable solution, its offspring will move closer to it to explore around the region deeply in following cross-over process.

3.2. Mutation

In this paper, mutation is to pick up two dimensions randomly. The chromosome's sequence between the two dimensions will be inversed. For example, there are two randomly selected dimension d_1 and d_2 in a chromosome. The contents (route sequence) between d_1 and $d_{2\,2}$will be re-arrangement.

3.3. Cross Path Detection

The goal of TSP is to find a route as short as possible.

Cross paths in route will serious increase distance in TSP. Although, evolution process of GA will find potential optimal solution. Unfortunately; it still may not be able to avoid such situation. In this paper, a geometry-based method called cross path detection is proposed. For current route, each path will be verified that if it cross to another path. These cross paths will then be eliminated.

Let's use symbol "a-b" denoting the path between city-a and city-b. For example, assuming there are 7 cities in TSP. Assuming the route of these cities is connected according to its serial numbers, and the path between city-1 and city-2 is selected for cross path detection. Thus the path 1-2 need to be compared with 3-4, 4-5, 5-6, 6-7. Note that the path 2-3 and 7-1 need not be compared with 1-2. Due to them will never cross to path 1-2. An example of cross path detection is shown in Fig. 1. In this case, the path 2-5 is cross to path 3-6. Thus, the city-2 will be connected to city-3 and city-5 will be connected to city-6.

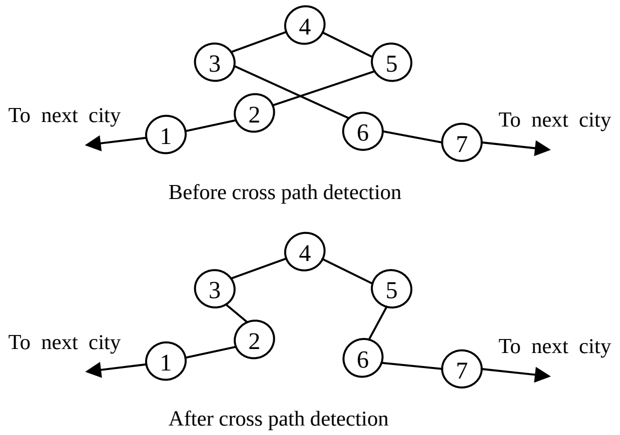

Fig. 1. Example for cross path detection

4 EXPERIMENTS

Ten TSP instances from the TPSLIB [5] were adopted for testing proposed method and compare it to Hybrid Genetic Algorithm [2] and Discrete PSO [1]. The parameters of these methods are set according to their original setting which are listed as following:

- Proposed Method
  The cross-over rate is 1 and the mutation rate is 0.85
- Hybrid Genetic Algorithm
  The cross-over rate is 0.5 and the mutation rate is 0.85
- Discrete PSO
  The inertia weight (w) is 1.49 and the accelerate coefficient (c_1 and c_2) are both 0.72.

All the four population-based optimizer were implemented using MATLAB 2010a. The maximal Number of Function Evaluations (FEs) is set to be 50,000 for all approaches. All algorithms were run 30 times and calculated their mean values and standard deviation for the results.

Table 1. Results of Ten TSP Instances

Instances \ Methods	Proposed method	Hybrid Genetic Algorithm	Discrete PSO
bayg29	9077 ± 6	9128 ± 70	12416 ± 822
st70	694 ± 4	699 ± 8	1141 ± 90
pr76	112749 ± 1544	112959 ± 1708	176556 ± 12538
rat99	1265 ± 5	1248 ± 14	2117 ± 131
eil101	671 ± 5	675 ± 8	996 ± 42
pr107	44494 ± 77	44683 ± 84	97344 ± 14619
ch130	6539 ± 66	6476 ± 99	11278 ± 792
kroA200	30676 ± 66	31479 ± 461	63030 ± 4124
ts225	132412 ± 1024	132647 ± 1243	209885 ± 10579
a280	2856 ± 23	2893 ± 40	4850 ± 23

Table I presents the mean and standard deviation of 30 runs for proposed method, Hybrid Genetic Algorithm and, Discrete PSO on the ten TSP instances. The best results among the four approaches are shown in bold.

From the results, the proposed method performed with better results can be observed. Furthermore, the proposed method surpasses all other algorithms in solving instances of bayg29, st70, pr76, eil101, pr107, kroA200, ts225 and a280. The Hybrid Genetic Algorithm performed better than proposed method on rat99 and ch130.

5 CONCLUSIONS

In this paper, the proposed method has been presented to solve travelling salesman problem (TSP). The cross path detection was adopted for untie the cross paths and for reducing route distance. Ten TSP instances of TSPLIB were selected for experiments. The experiments results show that the proposed method can find better solutions on these benchmarks than related works.

Abstract: In this paper, we present a new safety device to improve the safety of service robots for humans. The safety device consists of only mechanical components without actuators, controllers and batteries. The safety device is attached to each drive-shaft of a robot and locks the drive-shaft after detecting an unexpected robot motion on the basis of the drive-shaft's angular velocity. First, we present the design concept of the safety device. Second, we explain the mechanism of the safety device. Third, we show the developed safety device. Fourth, we experiment by using the developed safety device. Finally, from the experimental results, we discuss the usefulness of the safety device.

Keywords: Human-machine cooperative systems, Human-welfare robotics, Robotics, Safety device, Service robot

1 INTRODUCTION

Recently, there has been a growing interest in service robots which can support human daily activities. In industrial robots, safety of humans is implemented by isolating the robots from humans. However, in service robots, it is not possible to isolate the robots from humans because the robots work within human environments. Therefore, human safety becomes one of the most important issues in service robotics [1]-[4]. In this paper, we present a new safety device to improve human safety. The safety device consists of only mechanical components without actuators, controllers and batteries. The safety device is attached to each drive-shaft of a robot and locks the drive-shaft after detecting an unexpected robot motion on the basis of the drive-shaft's angular velocity. First, we present the design concept of the safety device. Second, we explain the mechanism of the safety device. Third, we show the developed safety device. Fourth, we experiment by using the developed safety device. Finally, from the experimental results, we discuss the usefulness of the safety device.

2 MECHANICAL SAFETY DEVICE

2.1 Characteristics of the Safety Device

The characteristics of the safety device are shown as follows:

(1) If the angular velocity of a drive-shaft (hereinafter referred to as "shaft") exceeds a preset threshold level, then the safety device for the shaft is activated. We call the preset threshold level "detection velocity level".

(2) The detection velocity level is adjustable.

(3) After detecting the unexpected robot motion on the basis of the angular velocity, the safety device switches all motors of the robot off.

(4) After switching off all motors, the safety device locks the shaft.

(5) The lock of the shaft is released by rotating the shaft in a direction opposite to the direction in which the safety device locks the shaft.

(6) The safety device consists of only passive components without actuators, controllers and batteries.

By the above characteristics (1), (3) and (4), we can expect that the safety device prevents high-speed collision between the robot and a human and reduces the collision force (see Fig.1 (i) and (ii)). Furthermore, by (2), we can adjust the detection velocity level according to the requirements for the given task. For example, when the

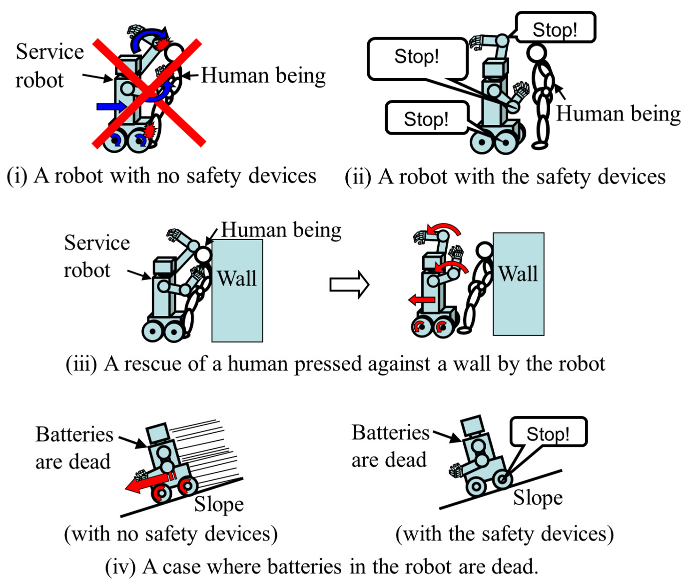

Fig.1 Characteristics of the safety device

robot is required to share workspace with humans in order to support humans, we can set the detection velocity level to low. When the robot is required to perform a high-speed task, we can set the detection velocity level to high and evacuate the robot's workspace. Additionally, by (5), if a human is pressed against a wall by the robot locked by the safety device, we can easily rescue the human by moving the robot in a direction opposite to the direction in which the human is pressed (see Fig.1(iii)). Finally, by (6), even if the batteries in the robot are dead, the safety device can act because it requires no power supply (see Fig.1(iv)).

2.2 Structure and Mechanism of the Safety Device

2.2.1 Structure

Fig.2 shows an example of robots equipped with the safety devices. As shown in Fig.2, the shaft of the robot arm is driven by the motor. In order to lock the shaft in clockwise and counterclockwise directions, two safety devices (one safety device for locking in the clockwise direction and another safety device for locking in the counterclockwise direction) are installed.

Fig.3 shows the structure of the safety device. Gear A, Plate B and Ratchet Wheel A are attached to the shaft of the robot arm. Claw B is attached to Plate B by Pin D. Guide Bar B attached to Claw B is inserted in Guide Hole B of Plate A. The shaft rotates Plate A via the torsion spring. One end of Linear Spring A is connected to Pin B attached to Plate C, and another end is connected to Pin A of Frame B. Plate C has Inner Teeth. Guide Bar A attached to Claw C is inserted to Guide Hole A of Plate C. Gear B meshes with Gear A. A rotary damper is connected to Gear B. Claw A is connected to the axis of the rotary damper. One end of Linear Spring B is connected to Claw A, and another end is connected to Frame A. Frame A is mounted on Frame B. Switch A which can interrupt electric power supply to all motors of the robot is installed at the position of being pressed by Pin C when Plate C is rotated. Fig.4 shows the details of Plate A. The ratchet teeth portion is connected to the plate portion via a spring.

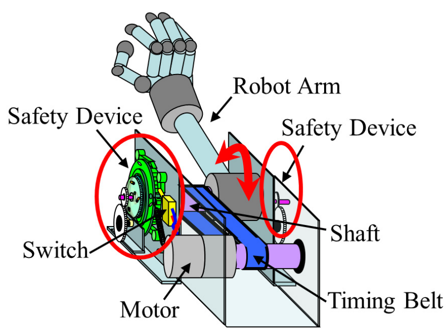

Fig.2 A robot arm with mechanical safety devices

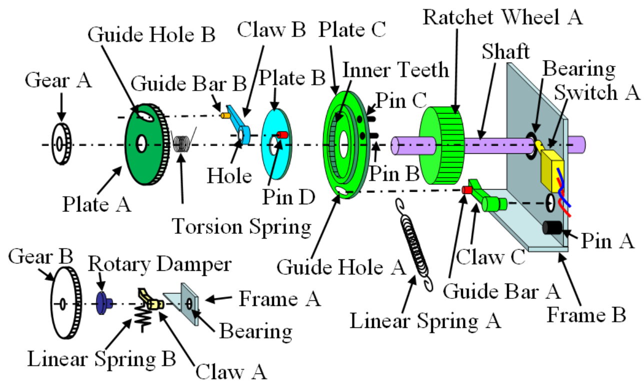

Fig.3 The structure of the mechanical safety device

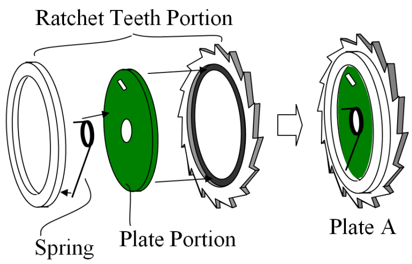

Fig.4 Details of Plate A

2.2.2 Mechanism

(1) Velocity-based detection mechanism

Fig.5 shows the mechanism which mechanically detects the unexpected robot motion on the basis of the angular velocity of the shaft. The damping torque by the rotary damper and the spring torque by Linear Spring B act on Claw A, when Gear B is rotated by Gear A. As the velocity of Gear A (shaft) increases, the damping torque increases. Claw A rotates by the torque difference between the damping torque and the spring torque, and locks Plate A, if the velocity of the shaft exceeds the detection velocity level. The detection velocity level is adjustable by changing the position where the end of Linear Spring B connected to Claw A is attached.

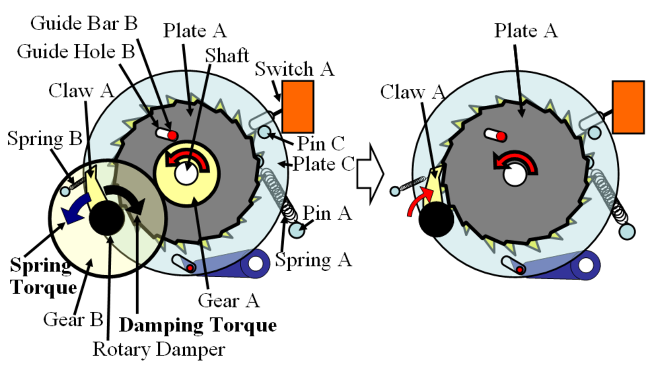

Fig.5 The velocity-based detection mechanism

(2) Shaft-lock mechanism

Fig. 6 shows the mechanism to mechanically lock the shaft. After Plate A was locked, Claw B slides along Guide Hole B of Plate A by the rotation of Plate B and contacts with the inner teeth of Plate C, as shown in Fig. 6(b). After contacting with the inner teeth, Claw B is hooked to the inner teeth and rotates Plate C (Fig. 6(c)). By the rotation of Plate C, Pin C switches off and Claw C moves along Guide Hole A (Fig. 6(d)). After that, Claw C meshes with Ratchet

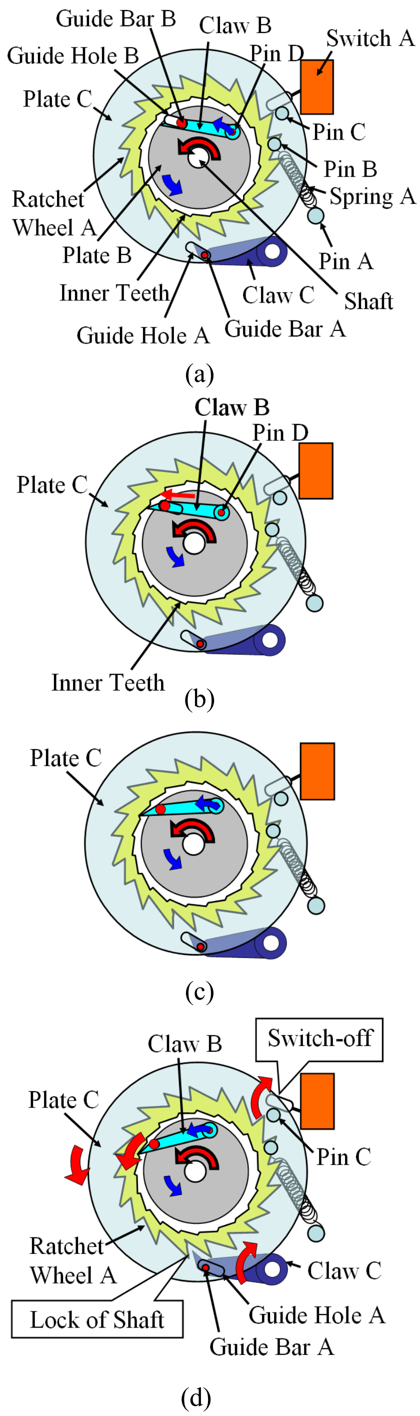

Fig. 6 The shaft-lock mechanism

Wheel A and thus the shaft is locked.

After the shaft is locked, the damping torque acting on Claw A becomes zero. However, if the gravitational torque generated by the arm acts on the shaft in the direction where the safety device is locking (see Fig.7), the lock of the shaft is kept by meshing between Ratchet Wheel A and Claw C. The lock of the shaft is released by moving the arm in the inverse direction.

After the shaft is locked, if the gravitational torque acts in the inverse direction to that of Fig.7 and the velocity of the shaft exceeds the detection velocity level in the inverse direction, the shaft is locked by another safety device for the inverse direction. If the velocity of the shaft does not reach the detection velocity level, the arm slowly falls down and stops in a state of being suspended from the shaft.

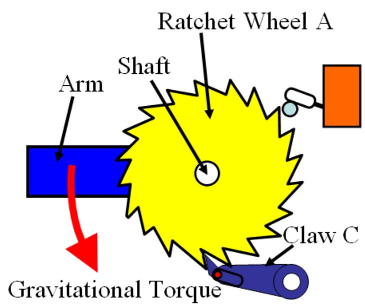

Fig.7 Lock of shaft

(3) Mechanism using three claws

In the above mechanism, in order to be meshed with Ratchet Wheel A and Claw C, it is necessary that the teeth number of Ratchet Wheel A equals the number of inner teeth of Plate C. It is preferred that the rotation angle of Claw B is as short as possible after Claw B contacts with the inner teeth of Plate C. As a method for shorting the rotation angle of Claw B, we can propose increasing the number of inner teeth on Plate C and the number of teeth on Ratchet Wheel A. However, there is a limitation on an increase in the number of inner teeth, because the safety device installed to robot is required to be as compact as possible.

In the following, we explain a mechanism using some claws. By using some claws, the mechanism provides the same advantage as when the teeth number is increased. Fig. 8 illustrates the mechanism in which three claws are used. Each claw is positioned as shown in Fig. 8(a). Lines 1, 2 and 3 trisect each tooth of the inner teeth. If Claw B_1 does not mesh with one of the teeth at the moment of contact, only with the movement of Claw B_2 by one third

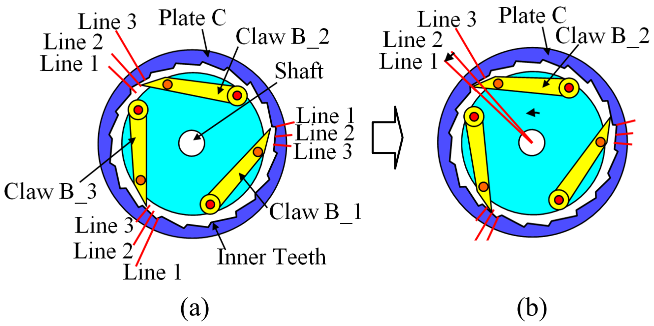

Fig.8 Three claws

of the tooth width, Claw B_2 meshes and rotates Plate C (Fig.8(b)). Note that, in this case, by using the Ratchet Wheel A having three times as many teeth as the inner teeth, Claw C is reliably meshed with the Ratchet Wheel A.

3 EXPERIMENT AND DISCUSSION

We developed the safety device using three claws' mechanism. We experimentally examined whether the shaft is stopped by the developed safety device after the angular velocity of the shaft exceeds the detection velocity level. Fig.9 shows the experimental setup. We attached some markers on the shaft and Claw A, then measured the positions of the markers by using a motion capture system (HAS-500, DITECT Corporation) while increasing the velocity of the shaft by the motor. The sampling frequency of the motion capture system was 200[Hz]. We experimented using a detection velocity level of 2.3 [rad/s]. The number of trials was 10. The angle of Claw A was approximately 0.21[rad] when Claw A locks Plate A.

Fig. 10 shows a typical example of the experimental results. Fig. 10 indicates that the shaft was stopped by the safety device after the angular velocity of the shaft exceeded the detection velocity level. The other results were approximately the same as this result.

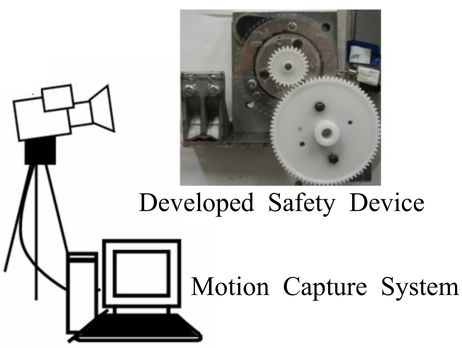

Fig.9 Experimental setup

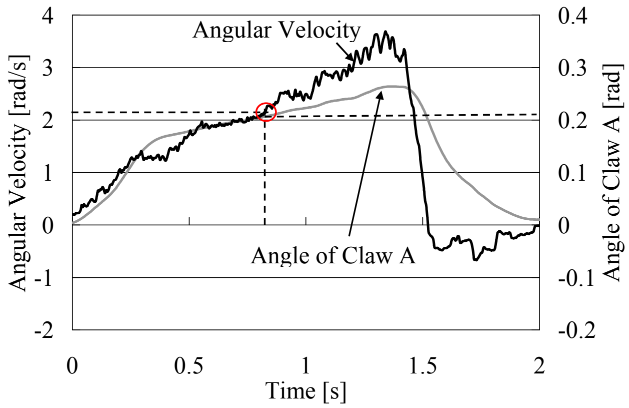

Fig.10 Experimental result

4 CONCLUSION

In this paper, we presented a new safety device to improve the safety of service robots for humans. Furthermore, we designed and developed the safety device. Finally, we experimentally examined the usefulness of the safety device.

ABSTRACT: Computer Generated Hologram (CGH) is made for three dimensional image of a virtual object that difficult to illuminate laser light directly. Even if this CGH deteriorate, it has characteristic that reconstruct is possible. This is a characteristic called the multiplexing that Fourier transform has. This characteristic is paid attention for the purpose of embedding this CGH as digital watermark because it is necessary to deteriorate this CGH. The purpose of this study is to make a computer authenticate CGH which we embedded it as digital watermark and took it out and regenerated. The method of the certification is Phase Only Correlation (POC). This study succeeded in improving the value of this evaluation.

1. INTRODUCTION

Computer Generated Hologram [1]~[3] (CGH) is made for three dimensional image of a virtual object that difficult to illuminate laser light directly. We uses dislocation model of CGH that be made relatively easily because it takes time to reconstruct three dimensional image even if use the fast algorithm. This dislocation model of CGH is demanded by calculating to Fraunhofer diffraction namely disintegration Fourier Transform. Even if this CGH deteriorate, it has characteristic that reconstruct is possible. This characteristic is paid attention for the purpose of embedding this CGH as digital watermark because it is necessary to deteriorate this CGH. This technique is used for the purpose of copyright protecting for digital image The digital watermark to use in this study is a frequency domain type. This technique has the characteristic that the SN ratio of an original image and an embedded image is higher. But this technique has a weak point. When the image which was made by this technique deteriorated, the embedded image not can be taken out. For example, it is the deterioration such as the weighted average filter. Therefore, we do not consider the deterioration of the image which was made by this technique in this study. The purpose of this study is to make a computer authenticate CGH which we embedded it as digital watermark and took it out and regenerated. The method of the certification is Phase Only Correlation (POC). POC is technique in consideration of only the form of the image. This method that pay attention to form includes a fault. It is that a correlation of O and similar form such as Q rises. This study tried improvement by doing image processing before taking the correlation of reconstruct image and original image to improve.

2. METHOD

2.1 MAKING Computer-Generated Hologram

The section explains the principle of the Fourier transform type hologram to use in this paper. For original image f(x,y), we perform a calculation equivalent to Fraunhofer diffraction namely disintegration Fourier Transform. The coordinate system of the original image defines it as (x,y). The coordinate system on the hologram side defines it as (u,v). When we perform this calculation, spectrum information is concentrated in the low frequency domain when we apply it for an original image. It is common to put random phase on original image f(x,y) to distribute this spectrum information for a frequency domain uniformly. Random phase ϕ (x.y) is random numbers of 0 - 2π. In other words, we regard a phase ingredient as important generated complex number information. Therefore, the computer hologram of the Fourier transform type is made by the following expressions.

$$F(u,v) = \frac{1}{\sqrt{N^2}} \sum_{m=0}^{N-1} \sum_{n=0}^{N-1} f(m,n) \phi(x,y) \cdot \exp\left\{ -j \frac{2\pi(mu+nv)}{N} \right\} \tag{2.1.1}$$

In addition, We perform this processing because it is known that gradation characteristics are compatible with the resolution of the reconstruct image by making F(u,v) 2 value by the following methods[4].

$$F'(u,v) \begin{cases} +1 & (\pi/2 \le \left| \arg F_S(u,v) \right|) \\ -1 & (otherwise) \end{cases} \tag{2.1.2}$$

$$F_S(u,v) = \frac{F(u,v)}{\max \left| \mathrm{Re}\left[F(u,v) \right] \right|} \tag{2.1.3}$$

Show the concrete processing result in the next section.

2.2 DIGITAL WATERMARK

This section explain frequency domain embedding type digital watermark to use in this paper. The frequency ingredient embedding type is the digital watermark which paid attention to that a high frequency ingredient of the Fourier transform is hard to look like human eyes. This method can embed CGH as digital watermark without affecting an original image more markedly than the masking type[5]. The information that is embedded by this method is poor at attack of compression father. But, the attack to the image after having embedded it does not consider it in this paper. Because we take first priority whether the certification of the reconstruct image is possible, in this paper use this method. Show below the processing results.

This study use the spectrum of the imaginary number to be born in the middle of this processing as a compound key. This is to suppress the deterioration of the image

2.3 PHASE-ONLY CORRELATION

Phase-Only Correlation [6] is a method to calculate a correlation that is made to do normalization to 1 of a provided amplitude ingredient by Fourier transform. Therefore, the method is not affected by the brightness value of the image. In other words the method was pay attention to the shape of the object in the image to compare only the phase ingredient of the image. show below a definition of Phase-Only Correlation.

Two images were put with f(x,y) and g(x,y) each.DFT is Fourier transform, they are as follows.

$$F\ (u,v) = DFT\left[f(x,y)\right] \quad (2.2.1)$$

$$G\ (u,v) = DFT\left[g(x,y)\right] \quad (2.2.1)$$

Phase information and amplitude information was expressed as follows. The amplitude ingredient was regarded as 1

$$F(u,v) = A_F(u,v)\exp(j\ \theta_F(u,v)) \quad (2.2.1)$$

$$G(u,v) = A_G(u,v)\exp(j\ \theta_G(u,v)) \quad (2.2.1)$$

Phase-Only Correlation was defined as follows

$$PH(u,v) = IDFT\left[\frac{F^*(u,v)G(u,v)}{\left|F^*(u,v)G(u,v)\right|}\right] \quad (2.2.1)$$

$F^*(u,v)$ This function is complex conjugate.

2.4 THE IMAGE PROCESSING

1. The pixel level of the image is made a 2 level.(The threshold is 128.)
2. When the value of the attention pixel is clearly higher than the value of the pixel of the circumference, the value of the attention pixel is changed to 0.
3. The image is processed by raster operation until the change of the image disappears.
4. The image is processed by the Laplacian filter. The outline of the letter is extracted in this way.
5. The image which was processed to division into four is used in only a left upper part.

Show below the processing results.

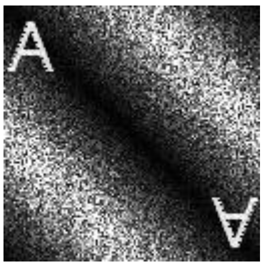

Fig 2.3.1
Before processing

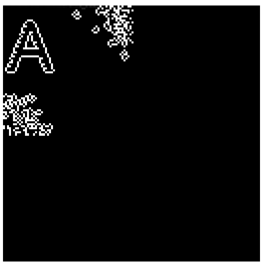

Fig 2.3.2
After processing

3. EXPERIMENT METHOD

1. Prepare the128*128 following images of "A" – "Z" form of the P-Gothic.
2. CGH which was made by a source image is embedded as digital watermark.
3. The embedded image is taken out. The image taken out is reconstructed.
4. The evaluation level by POC of the reconstruct image which nothing is made is compared with the correlative value by POC of the processed reconstruct image.
5. This study assumes the image which showed the highest correlative price a certification image.

4. RESULT

Show below the experiment results. It was revealed that original image and processed reconstruct image became highest. Characteristic examples of the correlative value by POC are "C" that is changed 0.087792897 to 0.150123, "E" that is changed 0.0532826 to 0.107673,"F" that is changed 0.0532826 to 0.094749.

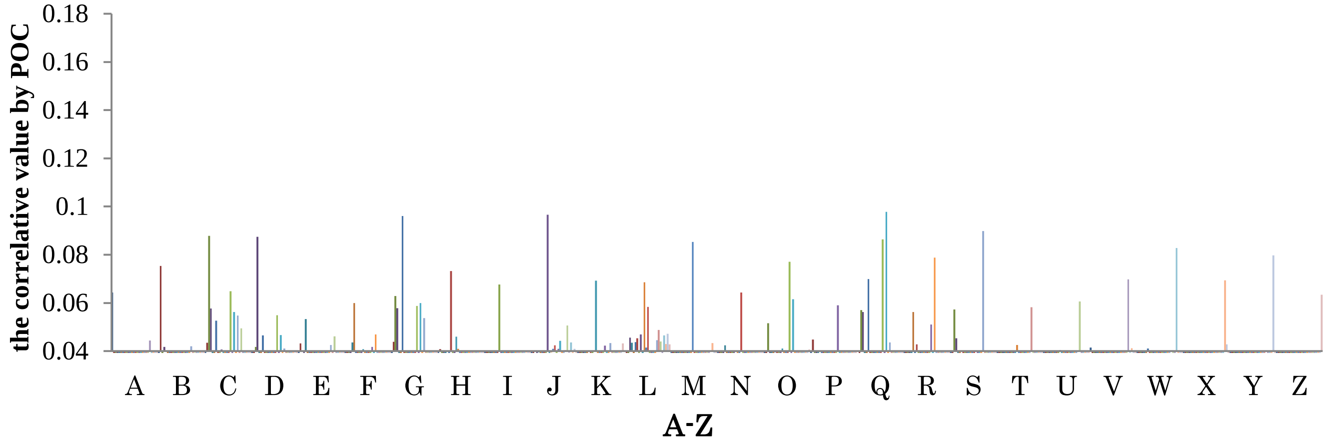

Fig 4.1 original - reconstruct

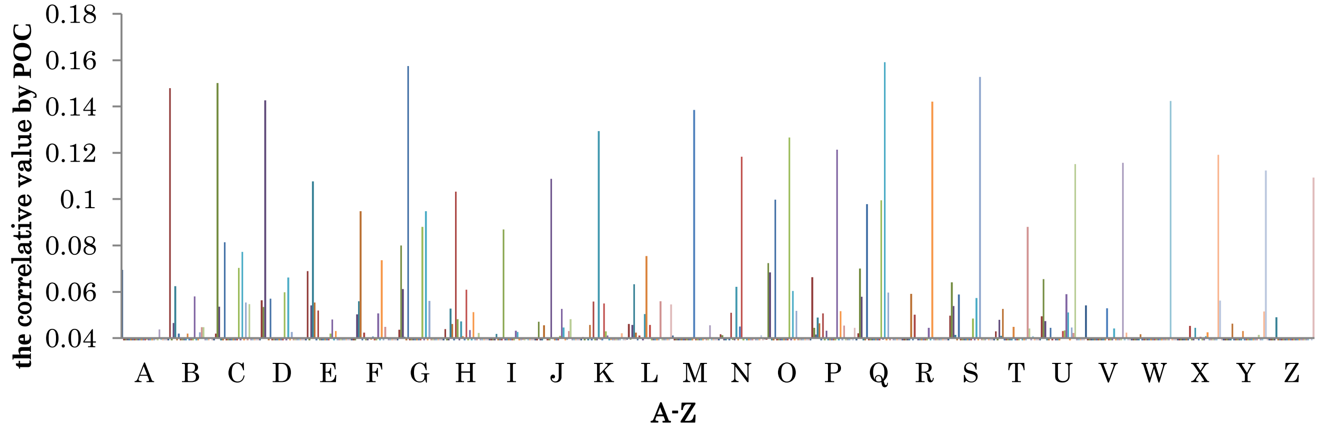

Fig 4.2 original - processed

5. CONSIDERATION

The correlative value by POC improved generally by performing the image processing that paid attention to an outline. The correlative values of character "E" and "F" improved very much. This improvement is able to authenticate it easily by computer. However, the correlative value such as character "A", "I" and "L" did not improve very much. It becomes the future problem to improve these values.

E-mail: ce01054@meiji.ac.jp

Abstract: When the image is displayed in the device that there is a limitation in the number of colors and the density value, the half tone processing is a needless technology. Several techniques like the dither method and the error diffusion method[1], etc. are proposed as a well known halftoning. The image evaluation of the processing image by the error diffusion method is superior compared with dither methods. Though, the processing image by the error diffusion method has visual problem. The blur is generated in the edge area. The noise of the striped pattern is generated in area that is low level value change of pixel. This paper, consider improvement the processing image by applying error diffusion algorithm with edge enhancement to using error coefficient corresponding to step edge. It is found that proposed technique process high quality halftoning image compared with error diffusion algorithm with edge enhancement.

Keywords: hlftoning, error diffusion, edge enhancement,

1 Introduction

Error diffusion algorithm with edge enhancement[2] is effect edge enhancement by determined threshold level for each pixel. Though, only this process, it is persisted that the noise of the striped pattern is generated in area that is low level value change of pixel. It is needed to solve this problem taking advantage of the Error diffusion algorithm with edge enhancement. In this paper, we consider the effectiveness that applying error diffusion algorithm with edge enhancement to using error coefficient corresponding to step edge.

2 Error diffusion algorithm with edge enhancement

In this section, describe error diffusion algorithm with edge enhancement briefly. Position of pixel being processed is put with (x, y), the pixel's value is g(x, y), the value that pixel processed is g'(x, y). Then g'(x, y) is as below.

$$g'(x,y)=\begin{Bmatrix}1 & g(x,y)\geq t(x,y)\\ 0 & g(x,y)<t(x,y)\end{Bmatrix} \tag{1}$$

t(x, y) is threshold level for each pixel. Enhancement coefficient is put with k, Standard threshold level is put with t', then t(x, y) is as below.

$$t(x,y)=(1-k)g(x,y)+kt' \tag{2}$$

Quantization error by processed is as below. This quantization error is diffused to neighborhood pixels as below.

$$error(x,y)=g(x,y)-g'(x,y) \tag{3}$$

$$(x',y')=(x',y')+W(x,y)\times error(x,y) \tag{4}$$

W(x, y) is diffusion coefficient that's range is 1 from 0. When k=1, threshold level for each pixel t(x, y) are same as standard threshold level t', it result in several algorithm error diffusion.

3 Reducing stripe noise using proper error coefficient

It is effective to solve the generated noise of the striped pattern that using large size error coefficient in area that is low level value change of pixel[3]. Though, in area pixel's value change high, the distance between the area generate quantization error and the area diffused quantization error is free. This causes the blur is generated in the edge area. Though, it is need to take the following measures.

1) In low level value change of pixel area, large size error coefficient is used.
2) In high level value change of pixel area, near the edge area, small size error coefficient is used.

Next section, describe the algorithm to search high level value change of pixel area to use above method.

4 Detection edge using differential filter

This study, we detect the edge using differential filter to search high level value change of pixel area. Differential filter outputs value change level of pixel as value of pixel, this is effective to search high level value change of pixel area. Differential filter are Fig.1, Fig.2. The value calculated by the differential filter is outputted as value of pixel, the image edge enhanced is displayed. (Fig.3). Value of edge is put with L(x, y), then L(x, y) is as below.

0	0	0
0	1	-1
0	0	0

Fig.1.

Vertical differential filter ⊿Y

$$L(x, y) = \sqrt{\triangle X(x, y)^2 + \triangle Y(x, y)^2} \tag{5}$$

Fig.3.
The image edge enhanced

5 Proposed method

It is summarized as follows : the proposed method.

1) The original image is detected the edge in advance.
2) Error diffusion algorithm with edge enhancement applied to the original image.
3) In near the edge area, small size error coefficient (Fig.4) is used. In low level value change of pixel area, large size error coefficient (Fig.5) is used.

It is used as small size error coefficient that is Floyd and Steinberg error coefficient(Fig.4). It is used as large size error coefficient that is original error coefficient(Fig.5). And also, near the edge area is defined as pixel that is detected the edge, and defined as 8 pixels surrounding the edge pixel is detected.

In the case, the quantization error by processed in low level value change of pixel area is diffused to near the edge by large size error coefficient, it is used small error diffusion the pixel.

g'(x, y) processed above method is displayed binary as blue, green, red. Error diffusion with edge enhancement algorithm and using error coefficient corresponding to step edge is complete.

6 Result

The original image is Fig.7. This size is 256×256. Value of pixel is 256gradations. It is difficult to judge visual problems like the noise of the striped pattern by numerical evaluation level [4]. There for, these problems are judged by visual. And level deterioration by binary is judged tone reproduction evaluation (MSE) [4], [5]. Standard threshold level is determined by discriminative analysis method [6], [7]. Discriminative analysis method is determiner considering background and object. There for, it is expected superior process in the vicinity monotonic area and edge area. Fig.8 is error diffusion algorithm with edge enhancement. Fig.9 is proposed method.

$$MSE = \frac{1}{MN}\sum (g(x,y) - g'(x,y))^2 \qquad (6)$$

Fig.7. Original image

Fig.8. Error diffusion algorithm with edge enhancement
MSE=22.5074846939085

Fig.9. Proposed method
MSE=22.1088512291146

Fig.9 is superior process in low level value change of pixel area than Fig.7. MSE is superior than Fig.8 of Fig.9 is more. From this, it is effective for tone reproduction evaluation that applying error diffusion algorithm with edge enhancement to using error coefficient corresponding to step edge.

7 Closing

It is effective for decrease the noise of the striped pattern and tone reproduction evaluation, taking advantage of the error diffusion algorithm with edge enhancement that applying error diffusion algorithm with edge enhancement to using error coefficient corresponding to step edge. In addition, it is found evaluation level (MSE) is depended on threshold level from this study. Future study, it is needed to consider that another determination threshold level.

Abstract: Differential evolution (DE) is a population-based optimization algorithm. The members of population in DE are called parameter vectors. Due to more real-world optimization problems become increasingly complex. Algorithms with more ability and efficiency for searching potential solution are also increasing in demand. Thus, in this paper, an improved DE is proposed for solving large scale global optimization. The proposed method is incorporated with the population manager to eliminate redundant parameter vectors or to hire new ones or to maintain population size according to the solution searching status to make the process more efficient. The proposed method also involves mutation and cross-over for prevent the solutions from falling into the local minimum and enhance searching ability.

Keywords: Differential evolution, population manager, optimization, traveling salesman problem.

1 INTRODUCTION

Due to more real-world optimization problems become increasingly complex. Algorithms with more ability and efficiency for searching potential solution are also increasing in demand. In last four decades, more and more heuristic-based algorithms were proposed for solving numerical optimization, such as genetic algorithm (GA)[1] and particle swarm optimizer (PSO)[2], etc. In 1997, the concept of original differential evolution (DE) was proposed by Storn and Price [3].

Differential evolution (DE) is a population-based optimization algorithm. The members of population in DE are called parameter vectors. There are four common mutation strategies of DE were developed [4][5]and shown as follows.

1. DE/best/1
$$x_n^{child_i} = x_n^{best} + F\left(X_n^{r_1} + X_n^{r_2}\right)$$
2. DE/rand/2
$$x_n^{child_i} = x_n^{r_1} + F_1\left(X_n^{r_2} + X_n^{r_3}\right) + F_2\left(X_n^{r_4} + X_n^{r_5}\right)$$
3. DE/target/1
$$x_n^{child_i} = x_n^{i} + F\left(X_n^{r_1} + X_n^{r_2}\right)$$
4. DE/target to best/1
$$x_n^{child_i} = x_n^{i} + F\left(X_n^{best} + X_n^{r_1}\right)$$

In this paper, an improved DE is proposed for solving large scale global optimization. The proposed method is incorporated with the population manager control population size according to the solution searching status. Also, improved mutation and crossover are involved for prevent the solutions from falling into the local minimum and enhance searching ability.

2 PROPOSED METHOD

The first thing to apply DE for solving different applications is to decide several initial parameters of DE, such as population size. Having more chromosomes can extend the searching space and increase the probability of finding the global optimal solution, but it will require more time in each iteration. The problem is that, until now, there is no way to know what size of population is suitable for solving the current problem. Here, a population manager (PM) is introduced into DE to enhance its searching ability. The PM will increase or decrease population size according to the solution searching status. Thus, the population size in the proposed DE is variable.

2.1 Population Manager

The population manager will increase or decrease particle numbers according to the solution-searching status; thus, the population size in DE is variable. If the particles cannot find a better solution to update the global best solution, particles may be trapped into the local minimum during the searching process or need a competent guide to lead them toward the potential area. Thus, the information (experience) of existing particles may be too little to handle the current solution-searching procedures. Thus, new particles should be added into the population to speedup the solution searching progress.

On the other hand, if particles can find one or more solutions to update the global best solution, the existing particles may too many. For saving some time on finding the global optimal solution, the redundant particles should be expelled from the population to conserve their evolution time for speeding up the solution-searching progress.

2.2. Mutation

In general, mutation is adopted to generate new chromosomes, mutate one or more genes, to save chromosomes that fell into the local minimum using random process, and to explore other potential searching spaces.

In proposed method, mutation is to randomly select a dimension (d_1) of the chromosome i and to perturb it in the range between minimal and maximal solution of another randomly selected dimension (d_2). This will ignore other dimensions but can fine tune the solutions of specific dimensions one by one in the chromosome. To share searching ranges of selected dimensions among particles can generate more potential solutions. In this paper, the mutation rate is increase linearly from 0.001 to 0.01.

2.3. Crossover

In proposed method, crossover is consisted of two parts, one is the same as original DE, and the other is one-cut point cross-over. The activating rate of them is 50-50 in first iteration. After that, the activating rate it will depend on their child's survival rate in previous iteration.

The one-cut-point cross-over is to randomly select a cut-point of particle, and to exchange the right parts of cut-point from two particles. Then, linear combination at the cut-point is performed on particles to generate new solution.

3 EXPERIMENTS

In the experiments, the IEEE CEC 2008 test functions [6], which includes two unimodal and five multimodal functions, were chosen for testing four variants of DE [4][5] and proposed method. Each test functions are set as 500 dimensions and run 25 times and calculated their mean values and standard deviation. The maximum fitness evaluations (FEs) were set as 2,500,000.

The results five variants of DE approaches on the seven test functions with 500D problems are presented in Table I. The real optimal values are also listed on right column of Table I. The best results among the five approaches are shown in bold. From the results, the proposed method surpasses all other algorithms on functions 1, 2, 3, 5, and 6. The DE/best/1 performed better than the proposed on functions 1 and 7. The proposed method can efficiently find better solutions than other algorithms in the same FEs.

4 CONCLUSIONS

In this paper, the proposed method has been presented to solve large scale global numerical optimization problems. The proposed population manager strategy can adjust population size according to its current solution searching state to ensure better (potential) parameter vectors will join the evolution of DE. It also makes DE more robust, prevents parameter vectors from falling into the local minimum. The experiments show that the proposed method can get closer to optimal solutions, and it is more efficient than other variant of DE on the problems studied.

Abstract: For human-robot coexistent environments, intelligent spaces including networked laser range sensors, cameras and the other sensing device have been developed. So, we consider the intelligent spaces with Fast-SLAM based on Particle Filter. Especially, on the map construction based on a grid map is more accurate than normal SLAM. However, those methods use only sensing data from the mobile robot to achieve SLAM. In this study, a new method of SLAM, which uses distributed sensors fixed in an environment as intelligent space, is introduced. This method shares information with SLAM of mobile robot. And we introduce calibration method of distributed sensors.

Keywords: mobile robot, SLAM, intelligent space

1 Introduction

Recently, as one of the methods for achievement of human-robot coexistent environments, intelligent space including distributed sensors has been considered [1][2]. In order to build intelligent space and to perform human tracking with distributed sensors, it is required to know positions of distributed sensors in world coordinate system of intelligent space. Then, calibration of distributed sensors must be achieved for development of intelligent spaces. However, it is generally complicated works. Easy calibration method is required for spreading the intelligent space. Especially, since distributed laser range sensors are widely used for human tracking in intelligent spaces, geometrical calibration of many laser range sensors in unified world coordinate system must be achieved. This study focuses on easy calibration of networked laser range sensors.

In this study, structural map building of intelligent space with a mobile robot is exploited for sensor calibration. Maps built by the distributed sensors are compared with the map built in SLAM process of the robot. Then, positions of the distributed sensors are estimated according to matching results.

Also, the map built by the robot is improved accurately according to estimation results of the distributed sensors. This study aims to improve position estimation of the mobile robot itself and the distributed sensors of intelligent space based on interactively communicating each other.

2 Interactive FastSLAM with intelligent space

2.1 Outline

In this study, FastSLAM[3] is used for map building by the mobile robot and localization. SLAM is a method to make a map of the environment, and estimate position of mobile robots simultaneously based on matching between sensing results and environmental maps previously generated. FastSLAM based on particle filter can achieve SLAM with high speed and high accuracy. Especially, grid-based Fast SLAM is more promising. This method includes building a probabilistic grid map based on environment information obtained by a laser range sensor on the mobile robot. Then, the grid map and new sensing results are compared every sampling time, and the grid map is updated. Mobile robot's self-position is also presumed based on this map.

This study considers extending FastSLAM by robot itself to an interactive SLAM with the intelligent space. The interactive SLAM uses grid-maps built by the networked laser range sensors of the intelligent space in addition to grid-maps built by robot itself. When the mobile robot is in the networked sensor's monitoring area, grid maps built by the networked sensors are shared with the mobile robot and used as the constraints of the mobile robot's SLAM. In that case, grid map by networked sensor and sensing results of the mobile robot are compared in each particle in addition to matching with local maps in SLAM process by robot itself with laser sensing results. Particles that match both maps will be preserved as good particles in the FastSLAM. This is effective for improving accuracy of grid maps,

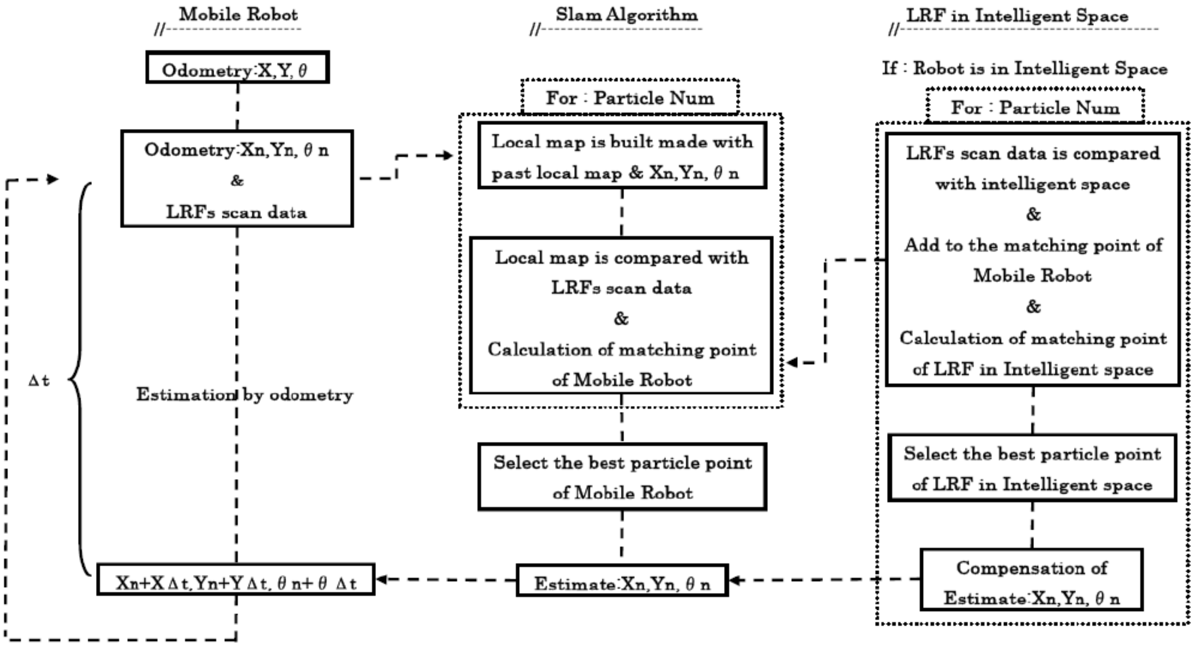

Fig.1 outline of interactive SLAM

because maps built by networked sensors fixed in the environments are integrated to map built by robot itself.

Next, it is assumed that positions of networked sensors in intelligent space are unknown. While interactive SLAM process, positions of networked sensor can be also estimated simultaneously in addition to positions of mobile robots.

2.2 System Configuration

System configuration of interactive SLAM with networked laser range sensors is shown in Fig.1. This system is configured with three processes: mobile robot control including data acquisition, SLAM process of mobile robot itself, mapping with distributed sensor.

In the robot control process, moving distance by odometry and range data by the sensor is measured for every sampling time. The measured data is sent to the SLAM process. At this time, the time stamps of sending data are saved in order to consider calculation time for estimation in the SLAM process. In the SLAM process, Grid Based FastSLAM is exploited for estimating robot positions and maps. Grid Based FastSLAM is based on a particle filter, and robot positions and maps are estimated as state variables. The computed state variable is retransmitted to the robot control process. Robot position in the robot control process is updated with considering the computation time for estimating position in the SLAM process.

Interactive FastSLAM is performed when a mobile robot moves in a monitoring area of a distributed sensor. Then, an occupancy grid map from the distributed sensor and a sensing result from a mobile robot are compared. Although matching between past maps generated by the mobile robot itself and the current sensing data is used for likelihood calculation of a particle in the usual SLAM, comparison with the map of the distributed sensor is also add in the interactive SLAM. Difference between a map estimated by the robot side and a map of the distributed sensor is reflected to estimation result of the interactive SLAM.

2.3 Construction of Grid Map in FastSLAM

Matching between current sensing data by the laser range sensor in the robot and a local map based on past position estimation is performed in map estimation of usual Grid Based FastSLAM. Likelihood is calculated based on the number of sensing points, which matched with the grids with high occupancy probabilities in the local map. This likelihood calculation is performed in each particle of a particle filter. Robot position is estimated by the weighting average based on likelihood of each particle. Fig.2 shows an example of the sensing data by the mobile robot in environment where moving objects, such as humans and the other static objects are exist. Fig.3 shows an example of matching between the sensing data and a local map. In this figure, red points represent grids that the local map and the sensing points are corresponding.

In comparison of Fig.2 and Fig.3, Fig.2 detects the moving objects in the measurement result. Since occupancy grid probabilities matched with any sensing points are updated in the grid map shown in Fig.3, influences of moving objects decrease in map building.

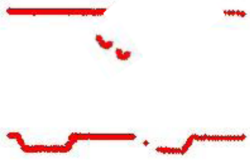

Fig.2 sensing result

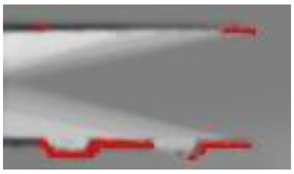

Fig.3 matching of local map and sensing data

2.4 Matching with maps by distributed laser range sensors

In the interactive FastSLAM using intelligent space, when a mobile robot moves into an area of a distributed laser range sensors, likelihood of each particle is computed from comparison with grid maps which the distributed sensors generate in addition to comparison with the local maps which the mobile robot itself generate as mentioned above. That is, when the mobile robot runs in the measuring range of a distributed sensor, it is aimed that accuracies of position and map estimations in SLAM process are improved by evaluating the matching points with the grid map from the distributed sensors. The grid maps of distributed sensors are generated by a method of literature [3]. Fig.4 is an example situation of matching with the map from the sensor fixed in intelligent space. In this figure, red points are current sensing points by the mobile robot. Blue points show the grids, which the map by distributed sensor and the sensing points are corresponded. It is enough when many correspondent points are measured as shown in Fig.4. However, as shown in left figure of Fig.5, there are many cases that correspondent points between the map by the distributed sensor and sensing data are small because of orientation differences between maps and sensing data especially. It means that the number of correspondent points is not enough to evaluate matching with the maps of distributed sensors.

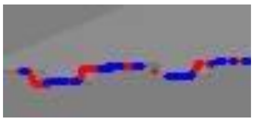

Fig.4 sensing data corresponding to map by a distributed sensor

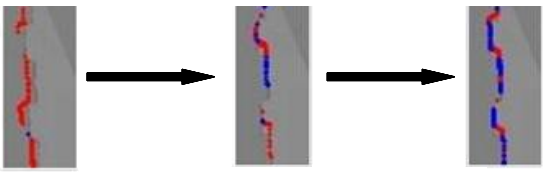

Fig.5 matching correction

So, in this study, orientation differences between maps of distributed sensors and sensing data are used for evaluation of matching. Two grids with the highest occupancy probability in the map of distributed sensor are selected as representative points. In the sensing data observed by the robot side, the points nearest to selected two points are searched. Average errors of two points are reflected to likelihood of each particle. At this time, each particle is also recording slopes of lines between each two points in the grid map or sensing data. State compensation based on the slopes is performed at the update of state variables in the robot side. Both the maps of distributed sensors and the map built by the robot itself are evaluated by performing this process for every cycle of the SLAM process. Matching result is corrected on running of the robot as shown in Fig.5. The number of matching points is shown by blue points increase in this figure. In the monitoring area of distributed sensors, particles, which match with both of the past local map by SLAM and the maps by distributed sensors will be selected as a result.

2.5 Estimating position and orientation of distributed laser range sensors

When positions and orientations of distributed laser range sensors in a world coordinate system are known, position estimation of a mobile robot and accuracy of map building improve according to the map of distributed sensors in the interactive FastSLAM as described above. In this case, the map of distributed sensors becomes constraints in SLAM process. However, when many sensors are distributed in the environment, it becomes a complicated work to know positions and orientations of all sensors in unified world coordinate system. Then, the case, that positions and orientations of distributed sensors are unknown, is considered. This study introduces estimating both positions and orientations of the mobile robot and distributed sensors simultaneously with interactive SLAM.

When a mobile robot enters into an area of distributed sensors, an initial position of the distributed sensor is measured by the mobile robot in the coordinate system of the map generated by the usual SLAM. A measurement result is sent to the distributed sensor. In Grid Based FastSLAM mentioned above, a mobile robot's position and the grid map are used as state variables. In addition to these state variables, positions and postures of distributed sensors are also added as state variables and estimated simultaneously. When the mobile robot runs into the areas of distributed sensors, correction of positions and orientations of distributed sensors are performed.

3 Experiment

As a preliminary experiment on the conditions which positions and orientations of distributed laser range sensors are known, the system of interactive FastSLAM is implemented and the experiment of self-position estimation and map generation was conducted. As experiment environment, the mobile robot moved a squared course in one floor of building of our university. A length of the course is about 100 m. Four distributed sensors were installed in yellow points of Fig.7. Fig.6 shows the map generated by usual FastSLAM only.

On the other hand, Fig.7 is a map built by information sharing with four distributed sensors with the interactive FastSLAM. A part of a red dotted circle in Fig.6 has matching errors when the mobile robot revisited this area. However, an accurate map is shown in a part of a yellow dotted circle in Fig.7, because the robot position and map are obtained by particles, which also matched with the maps from the intelligent space. Fig.8-11 is examples of map matching in the measurement areas of four distributed sensors in the interactive SLAM. These shows find that matching of a sensing result, a map by robot itself, and a map by the distributed sensor is performed in each part. Also, in the case that positions and orientations of distributed sensors are unknown, positions and orientations of the distributed sensors updated to actual values according to robot movement with the similar system.

In this experiment, the number of particle in a particle filter of the interactive SLAM is 50, and the grid size of is set to 50 mm x 50 mm. Pioneer3-DX was used for the mobile robot. UTM30-LX was used for the sensor installed in the robot. URG04-LX was used for the distributed sensors.

4 Conclusion

In this paper, it was shown that it is effective in improving the accuracy of SLAM by using information of distributed laser range sensors in intelligent space in the SLAM problem. This paper also described a possibility that the proposed SLAM is utilizable to estimating positions and orientations of distributed sensors in intelligent space.

Abstract: This paper proposes a human identification and tracking system with a wearable acceleration sensor and networked laser range scanners in an intelligent space. Human walking activities are measured and associated between laser range scanners and acceleration sensor. In this paper, a proposed person identification system between two types of sensors is described. A module of each sensor is implemented as RT component. The proposed distributed sensor system was developed by integrating these RT components. Information on walking behavior of human is communicated between components and shared in this system. Some experimental results with this system show a possibility of person identification and tracking.

Keywords: Acceleration sensors, Human identification, Human tracking, Intelligent Space, Laser range finders

1 INTRODUCTION

Recently, sensor network for configuring intelligent spaces has been actively studied [1][2]. There are various sensors, such as laser range sensors and cameras installed in the environments or mobile sensors with human in intelligent spaces. Especially, in order to support activities and understand behaviors based on movements of human in the environments, various methods to track the position of human have been proposed. Existing studies can be classified into three types according to properties of sensors.
(1) Vision sensor [3]
System with vision sensors can provide not only human position but also appearance and motion of human. However, they are lacking robustness, because false detections frequently occur due to change in lighting conditions or occlusions by obstacles in the environment.
(2) Laser range finders (LRF) [4]
LRFs have higher reliability and less noise signal because they are not affected by conditions in the environments. However, scan data obtained from laser range scanner cannot get personal identification. Therefore, when tracking multiple people, ambiguity occurs in identifying targets.
(3) Portable sensors [5]
Recently, small devices such as ID tags, acceleration sensors or other sensors have been developed, and they are often installed in mobile phones. Then, humans can easily carry such sensors. ID information can be easily associated to human based on information from mobile sensors. They are effective to ensure individual identification. However, position estimation with these mobile sensors is not accurate. In order to accurate position estimation with only mobile sensors, humans have to wear various kinds of sensors [5].
There are several studies as the solutions for obtaining human ID information and accurate positions simultaneously. Literature [6] shows that ID information can be obtained and human positions can be estimated accurately by integrating touch sensors or pressure sensors installed on the floor and acceleration sensors. Literature [7] shows person tracking and identification based on similarities between angular velocities obtained from gyro sensor with human and estimated by LRFs installed in the environment. In the literature [8], acceleration sensors and cameras installed in the environment are integrated. Correlation between movement of human extracted in images captured from vision sensors and acceleration signals from acceleration sensor with human are calculated.

This study developed a system which performs the person identification, and tracking based on the acceleration sensor with human and laser range scanners installed in the intelligent environment. A module of each sensor is implemented as RT component. The proposed distributed sensor system was developed by integrating these RT components. Information on walking behavior of human is communicated between components and shared in this system. Actually experiments of person identification using this system was performed. Experimental results show the validity of the proposed system. Fig.1 shows a concept of the proposed system.

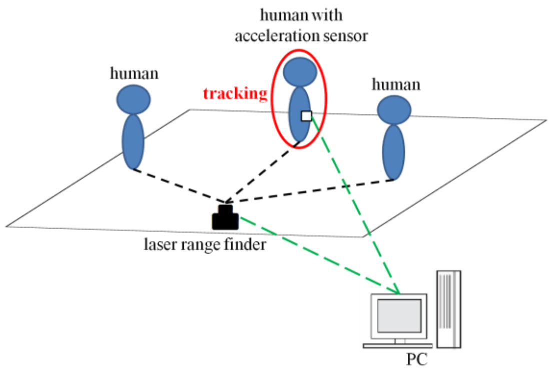

Fig.1 Concept f the study

2 TRACKING AND IDENTIFICATION SYSTEM WITH NETWORKED LASER SENSORS AND WEARABLE ACCELERATION SENSOR

In this study, human walking behaviors are detected in networked laser range scanners in the intelligent space and an acceleration sensor with human respectively. Walking behaviors of two types of sensors are associated according to steps of walking.

2.1 Walking detection using an acceleration sensor

First, the two low-pass filter (LPF, cut-off frequency: 0.5Hz, cut-off frequency: 10Hz) are applied to raw acceleration signals. LPF of 10Hz cut-off is used to eliminate the noise. In addition, DC components are obtained by LPF of 0.5Hz cut-off. DC components are treated as gravitational acceleration components. Fig.2 shows a vertical direction and a forward direction used for analysis of walking motion. If specific changes as shows as Fig.3 were appeared in the measured acceleration data, that motion is detected as "walking". Details of this "walking" detection are described in [9].

2.2 Walking detection using laser range scanners

First, moving objects are extracted by networked laser range sensors installed in the intelligent space calculating difference between current range data and background range data. Then, the position information of only moving objects are detected. Second, hierarchical clustering is applied to the extracted range data. After that, each moving object can be separated and tracked. Fig.4 shows detection and tracking of the human with two legs. If movements of detected human are bigger than threshold amount during a given period, the human is detected as "walking". Details of detecting and tracking human are shown in [10].

2.3 Matching based on walking behaviors

"Walking" behaviors are detected by networked laser range scanners installed in the intelligent space and the acceleration sensor with person. In this study, we focus on the occurrence and duration of walking and stopping. In the matching process, association between behavior detections by laser range scanners and the acceleration sensor are performed. The matching process evaluates whether "walking" behaviors at the same time are detected. A similarity of behaviors between two types of sensors is introduced to evaluate matching. A similarity s_{ij} is calculated with Eq.(1) to each combination of detections by acceleration sensor i and laser scanner j.

$$S_{ij} = 1 - 1/(1 + \exp(l_{ij})) \qquad (1)$$

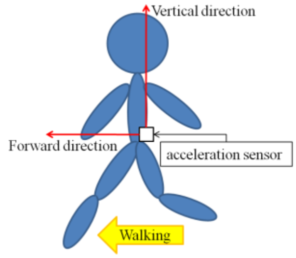

Fig.2 Axis definition of vertical direction and forward direction

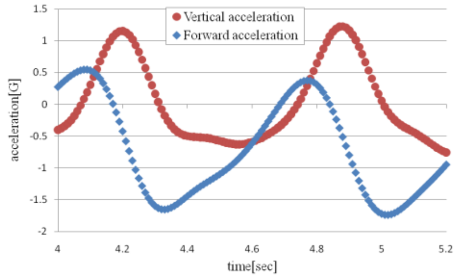

Fig.3 Acceleration change in one cycle walking

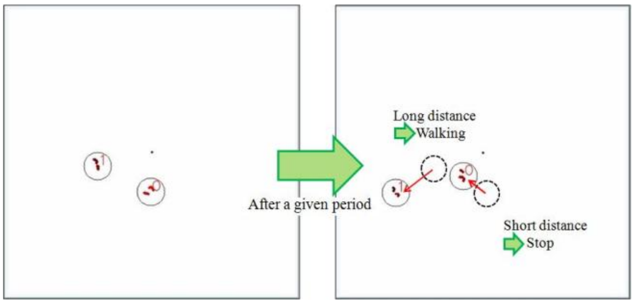

Fig.4 Human tracking and walking detection by laser sensors

l_{ij} changes based on behavior detections. If "walking" or "Stopping" is detected at the same time with both sensors, l_{ij} increases. On the other hand, when different behaviors are detected in both sensors, l_{ij} decreases. Then, a similarity also increases with same behavior and decreases with different behaviors from both sensors. Details of this matching method described in [11].

2.4 System development using RT component

The proposed system which performs walking behavior detection was implemented using RT middleware [12]. Each sensor module described in sections 2.1 or 2.2 was developed as RT component.

First, the component of acceleration sensor is explained. The component of acceleration sensor is executed at a computer set in the intelligent space. In the first operation "on activated", the component of an acceleration sensor reads default settings and connects to an acceleration sensor via Bluetooth from the computer that the component is running. In "on execute" process which it iterates acceleration data acquisition every 0.01 second. LPFs are applied to the acquired acceleration data, and removal of noises and calculation of gravitational acceleration are performed every loop. Acceleration data for calibration of human's forward direction is stored for the first 10 seconds after state transition to "on execute". Then, forward direction calibration is performed using principal component analysis based on acceleration data of the first 10 seconds. After 10 seconds, from two acceleration data, the vertical direction and the forward direction, walking behavior detection of the person with the acceleration sensor is performed. Results of walking behavior detection are transmitted to the other component. Flag "1" for walking behavior, or flag "-1" for stopping behavior as TimedLong type transmitted in this component.

Next, the component of laser range scanner is explained. In the first operation "on activated", the component of laser range scanner acquires range data used as a background. This range data is used for calculation of the background subtraction for extracting moving objects. In "on execute" process, human legs are detected from the moving objects as human. Position data of humans are acquired and the humans are tracked every 0.1 seconds. Walking or stopping detection results received from the component of wearable acceleration sensor is matched with walking or stopping behaviors of each tracking persons detected in the component of laser range scanner. A person with the best similarity is recognized to be a target person.

This system is based on small data communication between two sensor modules. Then, even if those who exist in the intelligent space increase in number, the system is executed by communicating only the information on walking or stopping detections.

Fig. 5 shows the structure of this system. The left is a component of an acceleration sensor. The right is a component of laser range scanner. Advanced components are required to handle many laser range scanners installed in the intelligent space in near future.

3 EXPERIMENT

3.1 System setup

Laser range scanners (Hokuyo Electric Machinery URG-04LX) are set at the height of about 25cm on a smooth floor. The target person wears the sensor (ATR-Promotions WAA-006) with gyro of three axes and acceleration of three axes on the waist. Components including the interface with each sensor and processing of walking detection are developed in each sensor by using the Open Robot Technology Middleware (RT Middleware) of AIST[12].

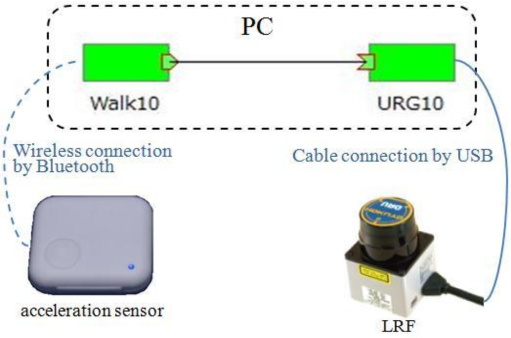

Fig.5 Wire connection figure of a system

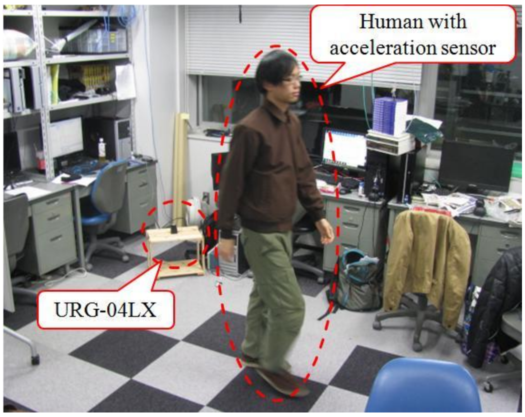

Fig.6 Experimental environment

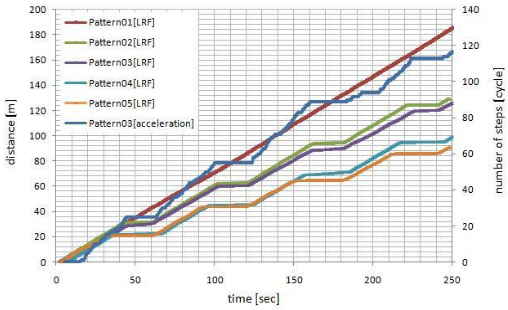
Detected results of "walking" are communicated between components. Fig.6 shows the experimental environment.

3.2. Experiments of human identification

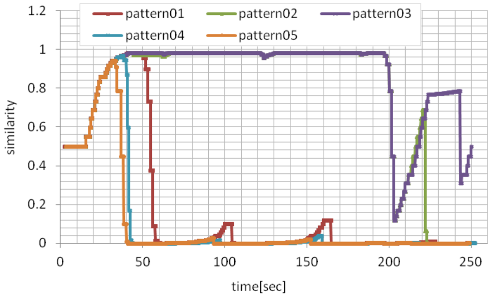
Experiments on identification of the target human with the acceleration sensor were performed. Five persons with the acceleration sensors walked around in the intelligent space. Laser range sensor is installed in the intelligent space for person tracking. Five persons walked and stopped as shown as Table.1 respectively. Pattern 02 and Pattern 03 are similar behavior. Pattern 04 and Pattern 05 are also similar. The algorithms for detecting correct persons in these similar behaviors are required for person identification. Seconds for walking or stopping were measured by a stopwatch. Fig.7 shows the examples of identification experiments among a target person and non-target persons.

Fig.7 also shows the case of Pattern 03 person. In this figure, the first vertical axis shows the walking distance measured by the laser range scanner, and the second vertical axis shows the number of walking steps detected by the acceleration sensor in [a]. This figure [b] shows similarity changes of all persons using the optimal parameters.

As shown in Fig.7, one of non-target persons performs a similar walking pattern compared with the target person (Pattern 03). In this figure, the similarities of Pattern 01, 04 and 05 were suppressed smaller than the similarities of



[a] Number of steps measured by acceleration sensor of target person and distance of five persons



[b] Grade of similarity of five persons

Fig.7 Results of five persons [Target is patturn03]

Pattern 02 and 03 after around 60 sec. Although it took more time to distinguish Pattern 03 with Pattern 02 than the other patterns, the highest similarity was obtained after around 200 sec.

This result introduce the association based on behaviors focused in this study has a possibility to identify a specific person from several persons and track him in high accuracy with laser range sensors in the intelligent space

4 CONCLUSION

This study aimed to identify a specific person with the accurate position measurements by integrating the networked laser range scanners installed in the intelligent space and an acceleration sensor with the person. This paper proposed the identification of a person based on associating the detections of walking behaviors from both sensors. Some experimental results showed the feasibility of the method. Improvement in accuracy of the decision of behavior in each sensor, and how to evaluate the similarity should be reconsidered in order to improve the performance as the future work. Experiments to identify the target from many persons should be performed.

Abstract: Three-dimensional position information is essential in order to give appropriate support for human beings in an intelligent space. Distributed cameras in an intelligent space have to be calibrated for acquisition of three-dimensional position. Since calibration of many cameras is time-consuming, camera calibration method for easy construction of an intelligent space is needed. This paper proposes automatic camera calibration method based on image features and 3D information of minimal calibrated cameras. Image features and 3D positions are shared with uncalibrated cameras via network, and these cameras are calibrated with common image features. In this paper, the first experimental results with SIFT (Scale-Invariant Feature Transform) as image features are shown.

Keywords: camera calibration, stereo camera, 3D reconstruction, mobile robot, intelligent space

1 INTRODUCTION

In recent years, there are many studies on intelligent spaces [1]. Fig.1. shows a concept of the intelligent space for acquiring information on positions and states of robot and person by distributing various sensors and networked cameras in the environment. It is necessary to know three-dimensional geometric relationship between networked cameras and environment in order to achieve various applications based on object positions in intelligent space. In other words, networked cameras must be calibrated geometrically in unified world coordinate system fixed to the environment.

Tsai's calibration method [2] needs to know several corresponding points between three-dimensional world coordinates and two-dimensional coordinates in image plane. Then, these must be measured manually in advance. Zhang's calibration method [3] needs artificial checker pattern. In this method, each camera is calibrated in the different world coordinate system. That is not enough for geometrical calibration of distributed cameras in unified world coordinate system. Since the calibration has to be performed for every camera, it is very time-consuming that human operators calibrate many cameras distributed in the environment with corresponding points or a plane checker pattern as usual. Even if intelligent space is large area, many cameras in the environment are desirable to be calibrated with small manual operation. These cameras must be also calibrated under unified world coordinate system. Camera calibration in unified coordinate system with cooperative positioning system [4] was proposed as a solution of such a problem. In this method, two robot-groups measure three-dimension position each other and move while measuring the other robot positions. On the other hand, geometrical relationship between cameras and environment can be also acquired with Structure from Motion (SFM), such as Parallel Tracking and Mapping (PTAM)[5].

This study introduces a calibration system under unified world coordinate system of networked cameras distributed in the intelligent space. The system uses a portable stereo camera and a mobile robot for calibration. World coordinates of natural corresponding points based on SIFT (Scale-Invariant Feature Transform) [6] are calculated according to localization of the portable stereo camera installed on the mobile robot. The detailed approach is as follows.

Self-position estimation of the mobile robot is used for localization of the portable stereo camera. World coordinates of natural feature points in stereo camera images are calculated using localization results. World coordinates of natural feature points are shared with the uncalibrated network cameras for calibration. However, camera calibration with natural corresponding points based on SIFT often fails. It is caused by that natural corresponding points are concentrated locally and that natural corresponding points include many mis-matched points.

It is desirable that successful calibration is distinguished from unsuccessful one easily by the human operator. In this study, the system for checking calibration conditions online is developed. This system includes matching of SIFT features, calculation of camera parameters, optimization of camera parameters and showing three-dimensional grids for representing calibration results online. Especially, matching of SIFT features take much processing time. In this study, online three-dimensional reconstruction of image features is achieved by fast calculation and matching of SIFT features with GPU.

Accordingly, the human operators of calibration system can calibrate the network cameras distributed in the intelligent space easily by moving the stereo camera on the mobile robot to front of uncalibrated network cameras. In this paper, detailed system configuration and performance of the system will be described.

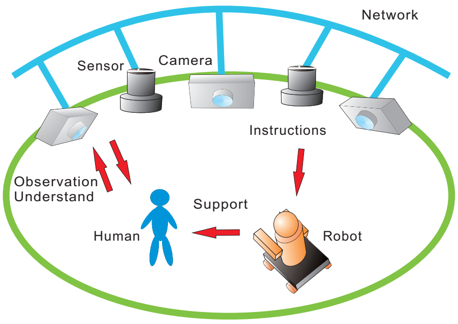

Fig. 1. The concept of the intelligent space

2 EASY CAMERA CALIBRATION SYSTEM

2.1 Proposed System

Fig.2. shows a flow chart of the proposed method. In this study, three-dimensional feature points measured by a portable stereo camera are used for calibration of networked cameras distributed in the intelligent space.

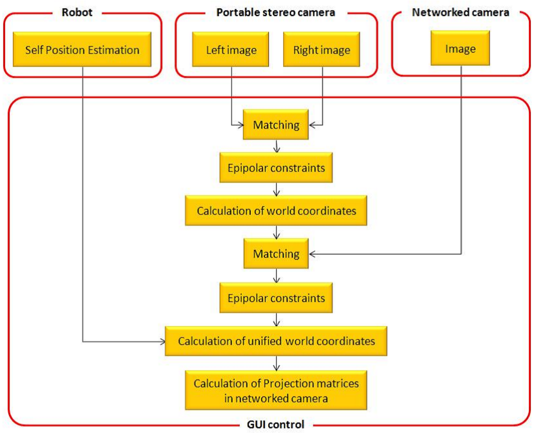

Fig. 2. Flow char t of the proposed method

2.2 Position Estimation of Portable Stereo Camera

A mobile robot with the portable stereo camera is manually controlled so that the view of a stereo camera can overlap with the view of a networked camera. Positions and orientations of the mobile robot are calculated by applying any self-position estimation algorithms of a mobile robot. Then, positions of the portable stereo camera in the unified world coordinate system can be obtained.

2.3 Matching of Feature Points

Matching points between images of a portable stereo camera and an image of a networked camera are calculated using SIFT features. Examples of many matched future points are shown in Fig.3..

However, several mis-matched points are found. These mis-matched points make an accuracy of estimating camera parameters of the networked camera worse. These mis-matched points are removed by a method based on epipolar restraint. Fig.4. shows results of removing mis-matched points in Fig.3..

Fig. 3. Matching of feature points among three images

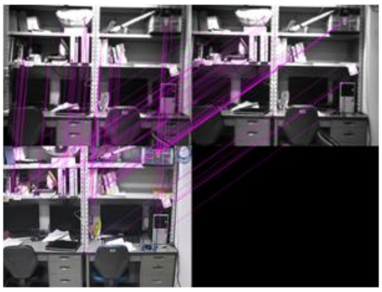

Fig. 4. Matching removed noise among three images

2.4 Positions in Unified World Coordinates

Fig.5. shows a method to calculate three-dimensional positions by the stereo camera in the camera coordinate system. Common feature points extracted by SIFT and epipolar constraints. Then, three-dimensional positions of feature points are calculated from stereo camera images. Of course, a geometrical relationship between left and right cameras of stereo camera is known.

Camera coordinates in the stereo camera must be transformed to unified world coordinate system. Fig.6. shows relationship between the camera coordinate system and the unified world coordinate system. Position estimation results of the mobile robot are applied.

2.5 Calculation of Camera Parameters

Camera parameters of the uncalibrated networked camera are calculated according to unified world coordinates of corresponding feature points between the networked camera and the stereo camera. However, camera parameters calculated

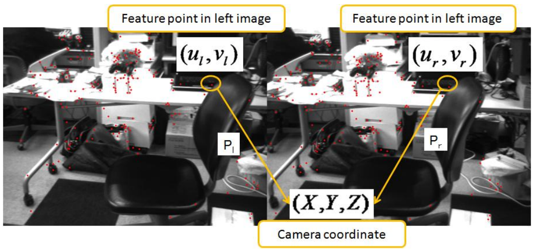

Fig. 5. Position calculation with stereo matching

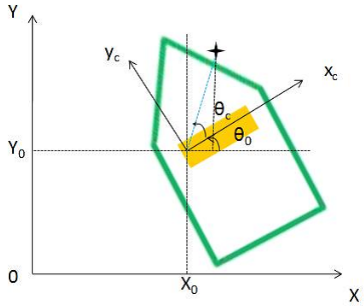

Fig. 6. Transformation between coordinate systems

in this level cannot reconstruct an accurate world coordinate system. Nonlinear optimization called Levenberg-Marquardt algorithm [7] is applied to optimize camera parameters. Details are shown in [8].

3 SYSTEM PERFORMANCE

3.1 Experimental Environment and Systems

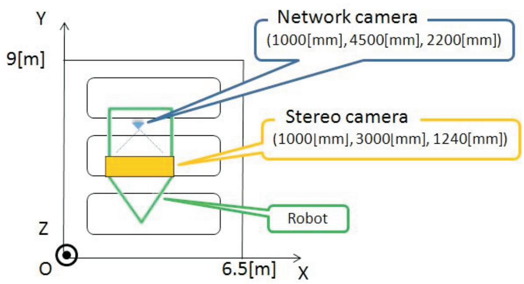

Fig. 7. Experimental environment

Position estimation of a moving stereo camera and calibration of networked cameras in the unified world coordinate system are performed as experiments. Bumblebee2 by Point Grey Research Inc. was used as the stereo camera. Canon VB-300 network camera was arranged in the intelligent space as the uncalibrated cameras for calibration experiment. Pioneer3-DX by MobileRobots Inc. was used as a mobile robot to mount the stereo camera. The stereo camera was calibrated using Zhangfs calibration method. All image sizes of cameras are 640 [pixel]   480 [pixel]. Fig.7. shows a sketch map of experimental environment. The Co-

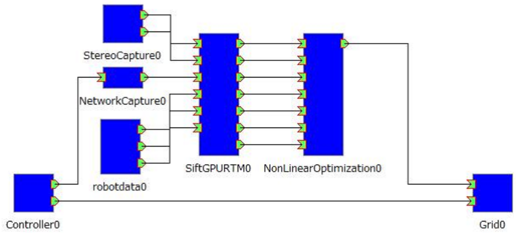

Fig. 8. Connection diagram of the system

ordinates (1000[mm], 4500[mm], 2200[mm]) and the coordinates (1000[mm], 3000[mm], 1240[mm]) mean unified world coordinates of networked camera and stereo camera. Fig.8. shows the connection diagram of this system with RT middleware. All modules of the system are implemented as RT components. A matching component is implemented with GPU processing. Since it achieves high speed matching, it enables to estimate camera parameters online. Camera parameters calculation in the developed system became faster around 30 times than a system with a normal CPU.

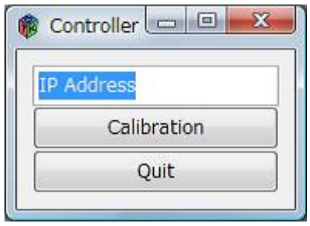

Fig. 9. GUI tool for calibration

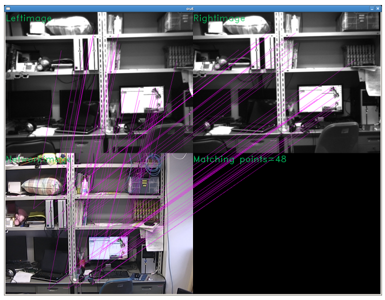

Fig. 10. Matching results

Fig. 11. Result of camera calibration

3.2 Calibration of Networked Cameras

A human operator controls the mobile robot to front of the target camera for making overlaps between the view of a stereo camera and the view of the networked camera. On a screen of computer, matching among the images of stereo camera and the image of networked camera, and three-dimensional reconstruction results are always displayed online. The human operator uses GUI shown in Fig.9. Calibration command is executed with this GUI when the accurate three-dimensional reconstruction results are displayed. Fig.10. shows results of matching. Fig.11. shows an example of three-dimensional reconstruction with calibration results.

3.3 Evaluation Experiment

Fig.12. shows an image of the target networked camera. In this figure, red points are selected and world coordinates of red points in the actual environment are measured manually for evaluations of calculated camera parameters. Green points represent the points projected using the world coordinates of red points and calibrated camera parameters. Errors between red points and green points are calculated. 1. shows the result of evaluation experiment. According to Table 1., there is the great difference between point where an error is small and point where an error is big. It is considered that is caused by that matching points concentrate locally. It can be used for the application like easy Augmented Reality (AR) which does not require highly precise camera calibration. There is room for improvement of this system. Concrete solution is introducing dynamic conditions so that matching points may be dispersively acquired according to a situation.

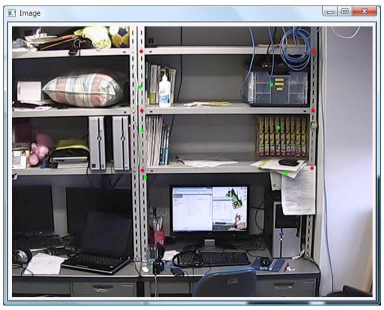

Fig. 12. Points for accuracy evaluation

Table 1. Result of evaluation experiment

Unified World Coordinates			Red		Green		Error
X[mm]	Y[mm]	Z[mm]	u	v	u'	v'	e
1040	470	1300	236	267	231	255	13.00
40	470	1300	486	261	532	251	47.07
1040	470	1650	231	184	230	149	35.01
40	470	1650	472	179	534	149	68.88
1040	470	2000	227	107	229	44	63.03
40	470	2000	460	103	535	44	95.43

4 CONCLUSION

This study proposed the camera calibration system in the unified coordinate system. The camera calibration method is based on estimating the position of the portable stereo camera and matching the feature points between the stereo camera and networked cameras.

Abstract: This paper presents development of a multi-purpose compact board for robot control systems and its applications. Advanced robot system with many actuators and sensors require complicated control system. Different sensor has different specification of signal output. Advanced robots have to accept many kinds of signals. Prototype robots in the laboratory are often extended and modified for the research. Common computer hardware for many kinds of actuators and sensors contributes to the efficiency of its software development. We have developed the multi-purpose Micro Control Unit (MCU) board that can be used for many kinds of actuators and sensors. The MCU board is designed so that it can be used for many devices and many applications. Two applications of the MCU board are presented to show its effectiveness.

Keywords: Distributed control system, Micro control unit, Robot control system, noise suppression

1 INTRODUCTION

Previously, large-sized computer boards and interface boards are used for control of various robots. These boards are so large that they are not easy to be located in the arms and legs of robots. Lots of long cables are required between the boards and various devices such as sensors and motors.

Recently, performance of small-sized one-chip microcontrollers is increasing. The microcontrollers have the function of CPU, RAM, Digital I/O, A/D converter and so on. Many kinds of microcontroller such as dsPIC by Microhip Technology Inc., H8 by Renesas Electronics Corporation, AVR by Atmel Corporation and ARM architecture are available for robot control.

Various MCU boards for sensing and control have been developed [1][2][3]. Lin at el. developed inertial measurement unit for human body motion tracking [1] and wireless inertial measurement unit for mastication analysis [2]. Faudzi et al. have developed the system using PSoC [3].

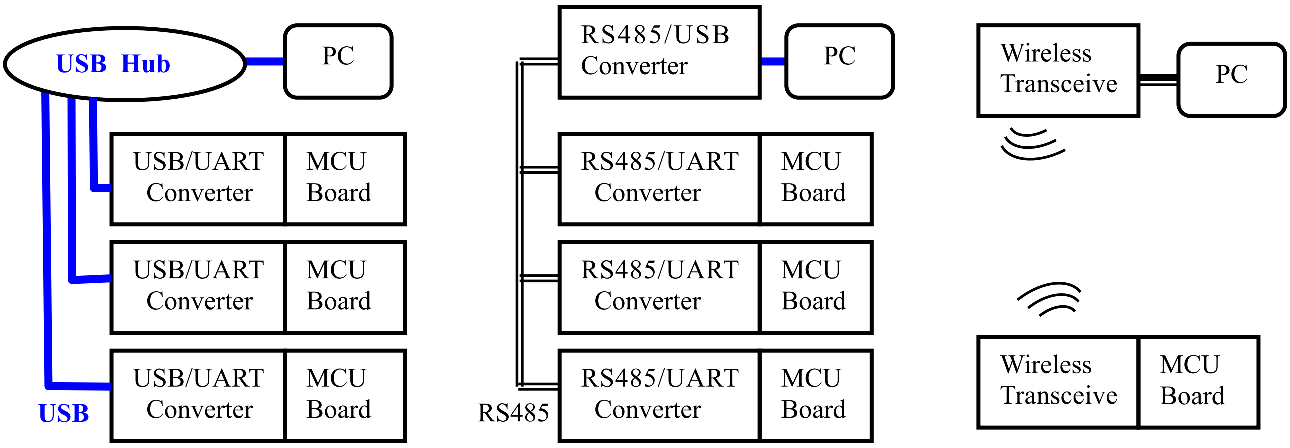
We have proposed the control system using a PC and MCUs (Micro Control Units)[4]. The PC are used for calculation of whole robot, and the MCU boards are used for local calculation and digital/analog interface. We also developed MCU boards [4] [5] and they are used in our humanoid robot [4], a robot hand [5], iWalker-2 [6] by Tanaka et al. and Omnidirectional Driving Gear by Tadakuma et al [7]. In this paper, a design and application of a new MCU board are presented. The board is more compact and more convenient than that presented in [5].

2 ROBOT CONTROL SYSTEM USING MCU BOARDS

If a MCU board can be designed for multiple purposes, various robots can be controlled using same boards. For a simple robot with a small number of actuators and sensors, stand-alone MCU board is embedded to control it. For a medium-scale robot, small number of MUC boards can be used for the control using communication standard such as UART (Universal Asynchronous Receiver Transmitter), I2C and SPI(Serial Peripheral Interface). For advanced robots using complicated control algorithms, PC are used for calculation. The advantages of PC are high computing power and wealth of software. The disadvantages of that are its largeness and high consumed power.

Hybrid system using a PC and MCUs are effective for robot control. The PC carries out complicated calculation and MCUs input and output digital/analog signals. Because many kinds of MCU have UART and most PCs have USB (Universal Serial Bus), a PC can communicate with MCUs using USB/UART shown Fig. 1 (a). Many MCUs can be connected with a PC using USB hub and maximum length of USB cables is 5 m. For large-scale robots such as humanoid robots, the control system using a PC, MCUs and RS485 (EIA-485) shown Fig. 1 (b) is effective [4]. Maximum length of RS485 cable is 1.2 km.

RS485 cable can be connected with MCU via RS485/UART converter. Conversion between USB and RS485 is possible by connecting USB/UART converter and UART/RS485 converter.



(a) system using USB (b) system using RS485 (c) wireless system

Fig. 1. Sensing and control system using a PC and MCU boards

MCU boards are desired to have the function of wireless communication shown Fig. 1 (c). For example, sensor network system to detect the human behavior is important for the robot control in human environment. Many MCU boards with sensors should be located in rooms. Many long cables for communication of MCU are inconvenient in the rooms. Wireless MCU board is easy to be located in the rooms.

MCUs for robot control are desired to have the many I/O function such as digital I/O, A/D converter, pulse counter, PWM output. A/D converters are used for reading the sensor signals. Pulse counters and PWM modules are used for feedback control of servo motors. D/A converter can be replaced by the integration of PWM and low-pass filter.

3 DESIGN OF MCU BOARD

Considering the requirements written in previous section, we have developed a new MCU board shown in Fig 2. Size of the board is 59 mm by 26 mm. A MCU, linear regulator, DC jack, pin headers, pin sockets for UART and pin sockets for writing program are mounted on a double-sided board. The MCU is dsPIC33FJ128MC204 by Microchip. Most of MCU pins are connected to the pin headers. The basic specification of the board is shown in Table 1. This board can control two DC motors with rotary encoders.

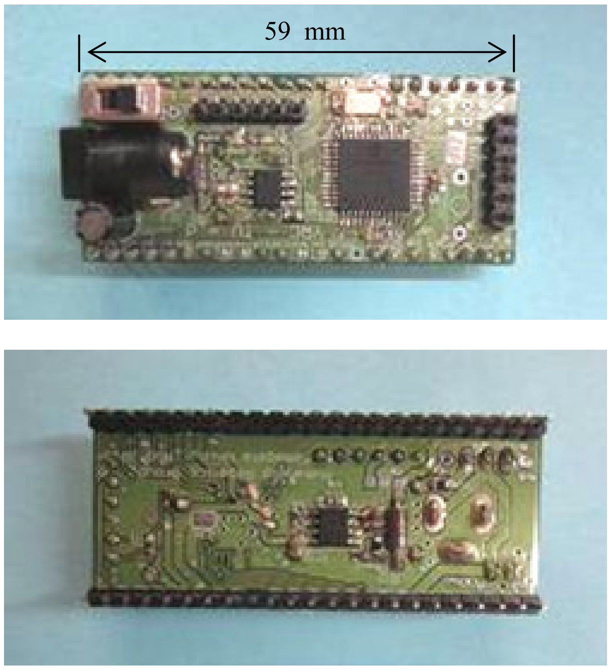


Fig. 2. Top and bottom biew of the MCU board.

Table 1. The specification of the MCU board

function	number of channels	main use
12bit A/D converter	9	Sensors
QEI counter	2	rotary encoders
PWM	8	H-bridge Circuits Analog input drivers
Digital I/O	32	Sensors and actuators
UART	2	USB, RS485, XBee
SPI	2	
I2C	1	

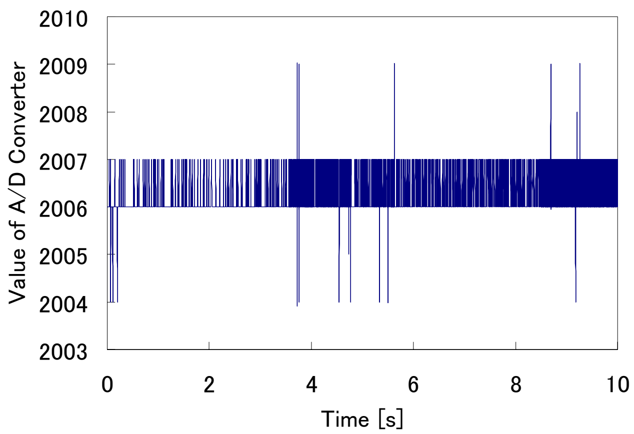

Fig. 3. The result of the experiment.

The pin sockets for UART is designed so that USB/UART converter "FTDI Basic Breakout - 5V" by Sparkfun Electronics or compatible board can be attached to it. The connecter for program writing is designed for the writer of PICkit2 by Microchip. The PICkit2 is connected a PC using a USB cable. Because the pitch of the pin headers is 2.54 mm, the board can be inserted to bread board or 2.54-mm pitch universal board.

The measure against noise is important for MCU board, because the noise have a bad effect on accuracy of A/D converter. To reduce power-supply noise, linear regulator and ferrite bead are utilized. The ground of analog circuit has a single connection to that of digital circuit so that the bad effect of the digital current to analog circuit is reduced.

4 EXPERIMENT

To evaluate the MCU board, we have performed an experiment. In the experiment, voltage of battery cell is measured in order to see the effects of noise. The result of the experiment is shown in Fig. 3. If the effect of the noise is large, variation of the voltage becomes large in the board. In 10 seconds, 4876 times A/D converter data were obtained. Maximum value was 2008 and minimum one was 2004. Most of obtained digital values were 2006 or 2007. Digital value of 2004 was obtained 10 times, 2005 was obtained once, 2008 was obtained once and 2009 was obtained 5 times.

5 APPLICATION OF THE MCU BOARD

We show two application of the MCU board. First one is the system to measure the current of DC servo motors. The photograph of the system is shown in Fig. 4 (a). Motor current is measured by hall effect-based linear current sensor IC. The IC output the voltage signal and the MCU measured the voltage using A/D converter. The values of A/D converter are transmitted to the PC via UART/USB converter.

The other application is sensing system of acceleration and angular velocity with wireless transceiver. The photograph of the system is shown in Fig. 4 (b). The system includes 3-Axis analog output acceleration sensor and analog output vibrational gyroscope. The acceleration sensor is MMA7361LC by Freescale Semiconductor, Inc. and gyroscope is ENC-03R by Murata Manufacturing Co., Ltd. The signals of acceleration sensor and gyroscope are obtained by A/D converter of the MCU. The MCU transmits A/D converter value using UART. For wireless communication, XBee by Digi International Inc. is utilized. XBee receives the data from UART and converts it to wireless signal.

6 CONCLUSION

The development of a multi-purpose compact MCU board has been presented. Requirements of multi-purpose MCU boards have been discussed. The design and specification of the MCU board have been presented. The experimental result of the MCU board shows that variation of A/D converter value is very small when the voltage of battery cell was measured. This result indicates that the bad effect of noise is small. Two applications of the MCU board show that the board can be used for multiple purposes. In future work, we will use the board for the control of a humanoid robot and sensor network systems.

Abstract: The 'cruise-and-collect' algorithm proposes in this research is intended to be applied for an autonomous robot system. The robot is designed to be used in a sport such as table-tennis, to help the players collect the off-side ball during a game. The controller for the robot system will utilize ARM-based microcontroller chip from Atmel, AT91SAM7S128, as it is the classic ARM7TDMI processor that had marked a great success of ARM processor market. The algorithm is developed via *Flowcode* software which exploits the flowchart as its design entry. The E-block board that has an integrated microcontroller chip is used for the purpose of its hardware prototype and software testing. It is hoped that the development and design process exposed in this research will be benefitted for researchers who are interested in the area of prototype development and robot design, especially via the ARM7TDMI processor platform**.**

Keywords: ARM-based processor, AT91SAM7S128, E-block, *Flowcode*.

1 INTRODUCTION

The concept of autonomous robot reflects that a robot can perform a desired task in an unstructured environment without continuous human guidance, or with minimal human control [1]. Depending on its application, the design approach might cover several modular areas; each carries a certain degree of autonomous in the robot's development.

In developing an autonomous robot for assembly line (typically used in warehouse or factory), the focus is given more to the assembly plan itself [2]. Successful assembly plan ensures that each of the pieces to be assembled in the warehouse is defined clearly in each of its single step. An algorithm related to each of these assembly steps are written such that the robot will perform those task consequently and independently. A feedback scheduling might also be provided in the algorithm to avoid repetition of its assembly step [2]. Compared to the design of an Autonomous Underwater Vehicle (AUV), the focus is more towards the navigational path of the autonomous robot because the robot is moving [3]. In this case, the algorithm design concentrates on collision avoidance and escape route by gathering the object geometries and its relative distance to the robot (reactive system). Furthermore, advancement to the reactive system was proposed, such that a configured database (known surrounding information and maneuver reaction) is added to the component. With this configured database, the reactive system will have additional information that helps the autonomous robot to plan for its navigational path effectively besides its real-time information gathering [3]. Later, the algorithm for autonomous robot navigation was improved, resulting in a real-time hierarchical POMDP (Partially Observable Markov Decision Processes) [4]. This improved algorithm act as a unified framework for autonomous robot navigation in dynamic environment, where it decides for the robot movement in every time step execution. The algorithm also caters for planning, localization and local obstacle avoidance; those are the traditional approach for an autonomous navigational system [2].

2 AUTONOMOUS ROBOT DESIGN ISSUES

Gathering from the literatures [2][3][4], there are several design issues need to be addressed in the development of an autonomous robot. For the purpose of this paper, only two of the design issues will be highlighted. The first issue is the navigational path of the robot; either it is predetermined or unknown. If it is unknown, several sensors need to be listed as part of the feedback circuit in configuring the robot's paths and movements. If it is predetermined, the navigational algorithm needs to be manipulated such that it reflects the predetermined path. The paths need to be clearly specified, so that the robot will be fully autonomous.

Next issue is on the definition of the application of the autonomous robot itself. As such, the algorithm and sensors related need to be configured to perform the required task. The application should also reflect the autonomous robot requirement in its design.

With these two design issues clearly described, the autonomous robot proposed in this research can be developed. Still, the core target in this project will not be forgotten that is, to explore the functionality of ARM-processor platform for robotics application.

3 DEVELOPMENT APPROACH

The prototype of the autonomous robot developed in this research is intended to be used in table-tennis (ping-pong) sport, as a ball-collector (applying the 'cruise-and-collect' algorithm in its system).

The prototype will take a route such that it will cover all the space along its way and collect the ping-pong ball. It is assumed that there is a wall at one side of the navigational path to ease the collecting work and the route is free from any obstacles as in **Fig. 1**. All those mentioned above are the 'cruise' information used in the algorithm of the system in this research.

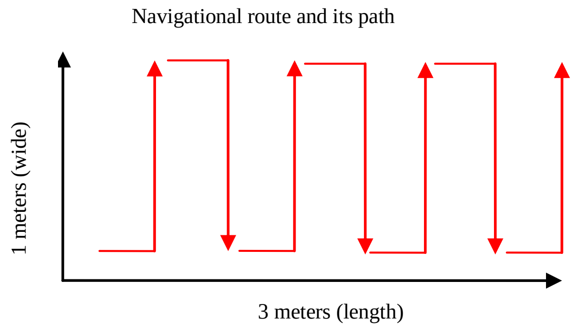

Fig. 1. Navigational path of the autonomous robot

As the application of the autonomous robot in this research is to navigate through its designated route while collecting the ping-pong ball along its way, several sensors needs to be used to realize this system. **Fig. 2** illustrates the block diagram of this autonomous robot prototype.

The Controller Module is the most important part of the autonomous robot as this module consists of the processor unit in the system. The Sensor 1 Module will cater the 'cruise' operation or its navigational route, while the Sensor 2 Module will cater the 'collector' operation. Sensor 3 is of no use at the moment because it is intended to be developed for further enhancement of the system. The 3 sensor modules are the input of the system, to be processed by the Controller Module, in order to produce the respective output to the Cruise Module and Collect Module.

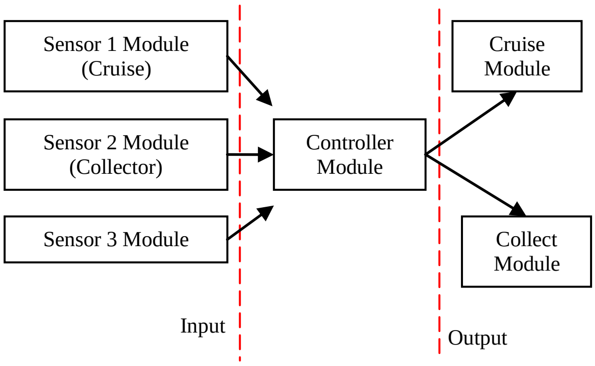

Fig. 2. Block diagram of the autonomous robot prototype

4 ALGORITHM DESIGN

The functional operation of the system is as summarized in the **Fig. 3**. **Fig. 4** detailed the flowchart of the Cruise Module, while **Fig. 5** shows the flowchart of the Collect Module. The Cruise Module inputs consist of 1 switch for prototype On/Off indicator, 1 switch for Start/Stop module and 3 IR sensors to guide the motor in its movement. The IR sensor act as the prototype eyes in order to avoid collision with obstacles in its surrounding. The Collect Module will make use of the same IR sensors in Cruise Module, such that it moves its motor to collect the ball in every turn the prototype made.

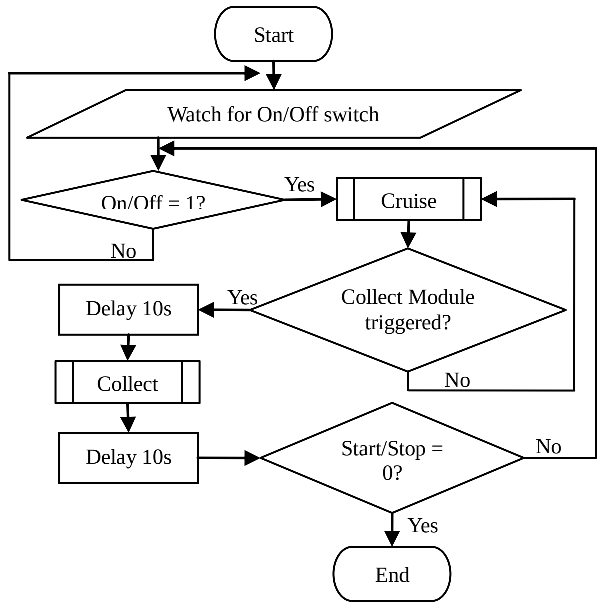

Fig. 3. Flowchart of the system operation

The designed algorithms as shown in the flowcharts are then realized via the *Flowcode* software, software that uses flowcharts as its design entry [5]. The *Flowcode* software has the capability to compile the flowcharts into the user's required form; either into Hex code, C-language code or compiled to the target board in the program. In this project, the designed flowcharts are compiled to its target board, EB031.

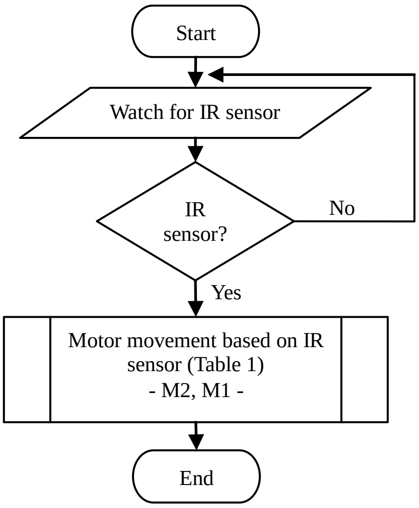

Fig. 4. Flowchart of Cruise Module

5 PROTOTYPE TESTING

The autonomous robot in this research is developed via the E-blocks boards, which can be obtained from *Matrix Multimedia Ltd.*, a company based in United Kingdom [5]. Due its low cost and free software download (trial version); these resources are chosen to be applied in this research.

The Controller Module will make use of EB031, an E-block ARM programmer board that is used to load the developed algorithm into the AT91SAM7 microcontroller chip. The microcontroller chip is housed on the removable EB034 board (another E-block), also called as ARM Daughter board. The removable ARM Daughter board allows users to detach the board and have the freedom to develop their own ARM application circuit. Both EB031 and EB034 board are as shown in **Fig. 6**.

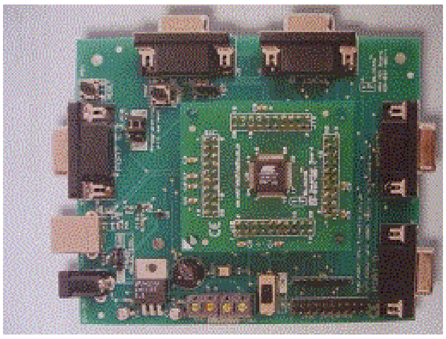

Fig. 6. EB031 and EB034 E-blocks

The supply voltage for EB031 board is an external regulated 6-9V DC supply or powered via the USB port (attached to computer) [6]. The programmer board is connected to any of its required input and output peripherals via its 5 serial ports (Port A, B, C, D and E). In this research, a motor driver board EB022, as shown in **Fig.7** is needed to drive the DC motor for wheel movement [7].

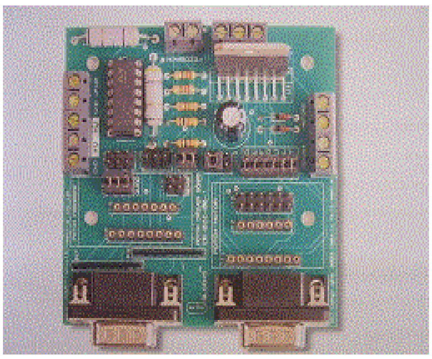

Fig. 7. EB022 E-block

The EB022 board allows users to drive two motors simultaneously and also allow independent PWM control for each motor. This board needs an external supply of minimum 5V and also for the motor power supply in the range of 3.3-24V external DC source.

For the purpose of this paper, the IR sensor status will be simulated via the LED board EB004 (**Fig. 8**) as the intended circuit is still in its development phase at the time of this paper writing. With that, the Collect Module will also be simulated via the LED pattern display.

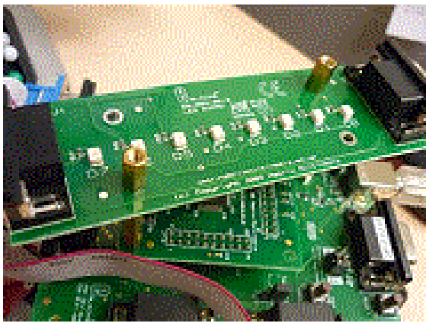

Fig. 8. EB004 E-block

The developed prototype is as shown in **Fig. 9.** With the EB031 and EB034 as the Controller Module, the EB004 will imitate the Collect Module while the EB022 will perform the Cruise Module. In this paper, the IR sensor condition is predetermined in the developed program as the IR sensor circuit is not fully developed at the time of this paper writing.

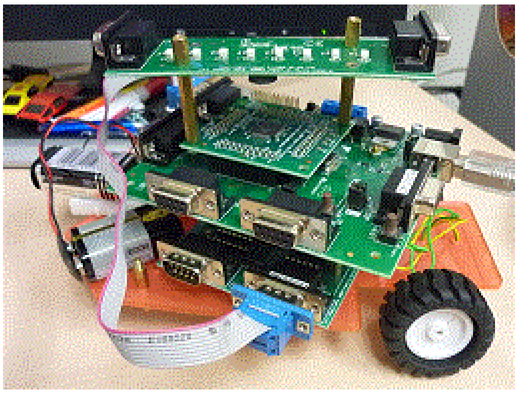

Fig. 9. Autonomous robot prototype

6 OBSERVATION AND CONCLUSION

From the developed prototype, it is observed that with a limited time constraint, researchers or even hobbyist may design their own application and develop the prototype with the use of the E-blocks and *Flowcode* software. The only constraint with the use of E-blocks is that each block must be connected via the serial port or E-block IDC cable if extension to the peripheral connection is needed. However, the removable ARM Daughter board allows customized circuit to be developed, besides restricting the development with only 5 serial ports given on the E-block ARM programmer board.

The 'cruise and collect' algorithm in this research is realized via the flowcharts without the hassles of writing the programming code. In this case, the steps involved in the development phase had been reduced, such that the system designer will only concern on its design requirement, but not the syntax or coding error. The use of flowcharts as the design entry form for the *Flowcode* software help ease the researchers work in testing its prototype. As such, the functional application can be fully tested and verified.

It is hoped that the development tools and design approach exposed in this paper will give the researchers or prototype developers other options in developing their system.

7 ACKNOWLEDGMENT

The authors would like to express the greatest appreciation to the Universiti Teknikal Malaysia Melaka (UTeM) for the continuos support, assistance and help given in completing this research.

***Abstract*— Diabetic retinopathy is an eye problem that face by the diabetic's patient. Diabetic Retinopathy (DR) is caused by the changes of the blood vessel in the retina. In the early stage of DR, the blood vessels may swell and leak fluid. However, in the advance stage of DR a new blood vessel that fragile and abnormal may formed and leaks blood to the retina. This can caused vision loss or even blindness. Therefore, this paper proposed to extract the blood vessel based on the peak and valley detection. The proposed methods utilized a green channel image and the inversion image. Next, the resulting images from both methods are combined. Three (3) databases are utilized namely from STructured Analysis of the Retina (STARE), Digital Retina Images for Vessel Extraction (DRIVE) and a database that is acquired from the local hospital.**

***Keywords*— blood vessel, diabetic retinopathy, peaks detection and valley detection.**

I. INTRODUCTION

Blood vessel appearance is a vital indicator in several diagnosis namely diabetic retinopathy, hypertension and arteriosclerosis. In this paper, the main focus is DR. Due to the increasing growth of interest in medical image processing, an automated detection of blood vessel in fundus images for diabetic retinopathy's patient is proposed. Retinopathy is a general term refers to some form of non-inflammatory damage to the eye in the retina. DR can lead to several abnormalities and the abnormalities are not connected to other structure on the retina are microaneurysms (MA), haemorrhages (HR), exudates (EX) and cotton wool spots (CWS). These abnormalities present in the early stage of DR known as Non Profilerative Retinopathy (NPR). Meanwhile, Proliferative Retinopathy (PR) is an advance stage of DR. In PR, a new blood vessel may grow and the new vessels are abnormal and very fragile. By themselves, these blood vessels do not cause symptoms or vision loss. However, if they leak blood, severe vision loss can result.

There are three (3) main methods that can be generally classified for blood vessel detection; window-based, classifier based and tracking based [3]. Kirbas [7] on the other hand did a survey in vessel extraction technique and algorithm. In his paper, 6 categories are classified; pattern recognition techniques, model-based approaches, tracking-based approaches, artificial intelligence-based approaches, neural network-based approaches, and tube-like object detection approaches. For pattern recognition techniques, it have been sub categorised to multi-scale approaches, skeleton-based approaches, region growing approaches, ridge-based approaches, differential geometry-based approaches, matching filters approaches and mathematical morphology schemes. For model-based approaches, three (3) subs have been classified; namely deformable models category, parametric models and generalized cylinders approaches. This paper utilized mathematical morphology that can be categorised in pattern recognition based on Kirbas's survey [7].

Reza [8] proposed to employ Quadtree method to detect the blood vessel in RGB using RGB component. [8] stated that the proposed method can yield true positive fraction values as high as 0.77, which are comparable to or somewhat higher than the results obtained by other known methods. Vallabha [10] utilized scale and orientation selective Gabor filter banks. This proposed method classified the retinal image as mild or severe based on the output obtained by Gabor filter. Localized adaptive thresholding and a multi-window Radon transform are utilized in detecting the vascular system in retinal images. The algorithm was tested with 20 images (10 normal and 10 abnormal) and the result demonstrated that an average positive rate of 86.3% and false positive rate is 3.9% [5, 6]. Meanwhile, local and global features cooperatively to segment the vessel network was proposed by Hoover [3]. Gaussian matched filter is designed and used to locate the center point and width of a vessel in its cross sectional profile. Next, extended Kalman Filter is employed for the optimal linear estimation of the next possible location point. Afterword, branching detection strategy is proposed to check the bifurcation [2]. Jiang [4] proposed a general framework of adaptive local thresholding based on a verification-based multithreshold probing scheme. The proposed method demonstrates a superior performance on normal compared to abnormal. Recently, Xu[11] also proposed to use adaptive thresholding and then extract the large connected component as the large vessels. The residue fragments are classified using Support Vector Machine. The average sensitivity obtained is over 77%. Sukkaew [9] proposed a method applies a Laplacian of Gaussian as a step-edge detector based on the second-order directional derivative to identify locations of the edge of vessels with zero crossings. Chaudhuri proposed two (2) dimensional matched filters to detect the blood vessel [1]. The main focus in this paper is to detect the blood vessel utilizing morphological operation. Three (3) databases are utilized namely the online database known as STARE, DRIVE and a custom database that is acquired from a local hospital. All the databases have different illumination and contrast. These variations are the constraints in previous works. In this paper, the research methodology is present in Section II followed by experimental results in Section III and last but not least the conclusions.

II. RESEARCH METHODOLOGY

Numerous methods have been proposed in previous works. The matched filter, Gabor filter and morphological filtering are the most well-known approach. In this paper, peak and valley detection based on half sphere is proposed. The main different is this proposed method makes use of the inversion of the green channel image to detect the peak. The proposed method for blood vessel detection is illustrated in Fig. 1.

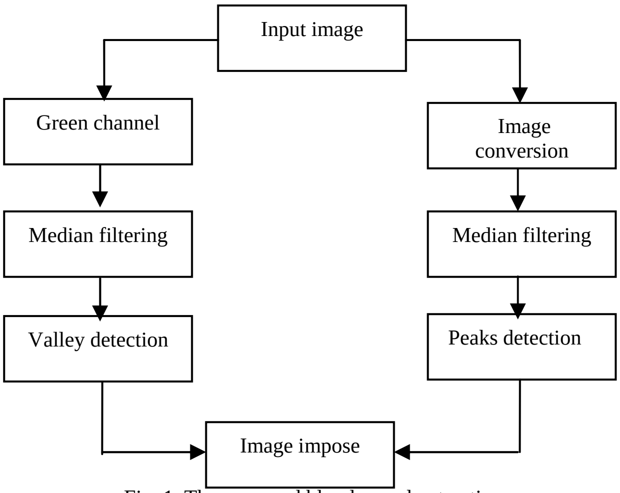

Fig. 1 The proposed blood vessel extraction

A. *Morphology*

Peak detection algorithm is a type of morphological processing. There are several type of structuring element that can be applied such as circle, sphere and square. In this paper, half sphere structuring element is applied.

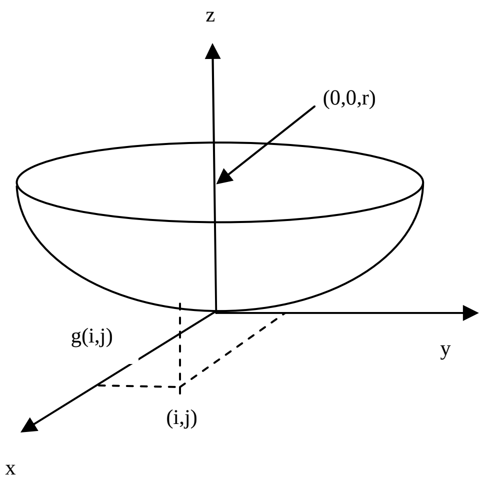

Fig. 2 Half sphere structuring element

If the radius of the sphere is r, G is given by:

$$G = \{ i, j, g(i,j) \} \quad -r \leq i \leq r$$
$$-\left\lfloor \sqrt{r^2 - i^2} \right\rfloor \leq j \leq \left\lfloor \sqrt{r^2 - i^2} \right\rfloor$$

for all i and height;

$$g(i,j) = \left\lfloor r - \sqrt{r^2 - i^2 - j^2} \right\rfloor$$

for all j. where $\lfloor a \rfloor$ denotes the greatest integer smaller than or equal to a real number of G. Given the following definition:

$$I(x,y) \; (0 \leq x \leq m-1, 0 \leq y \leq n-1)$$

- I(x,y): the original image,
- r: radius of the sphere,
- $\lfloor a \rfloor$: the largest integer smaller than or equal to a,
- m,n: is the length and height of the image.
- $\max f(i,j)$ means the maximum of $f(i,j)$ over all the points (i,j) inside G.
- $\min f(i,j)$ means the minimum of $f(i,j)$ over all the points (i,j) inside G.

Peak detection algorithm is an opening morphology. Erosion is performed first then followed by dilation. Peak detection algorithm is simplified as follows;

- Find point (i,j) in half sphere r, find corresponding value of g(i,j)
- Grayscale erosion is performed onto each pixel and obtained R(x,y)
  R(x,y):=max{I(x-1,y-1) + g(i,j)};
- Perform grayscale dilation and obtained D(x,y)
  D(x,y):=min{R(x-1,y-1) - g(i,j)};
- Perform P(x,y) = I(x,y)-D(x,y) for each pixel (x,y)
  P(x,y) = 1 if (x,y) is a peak pixel
  P(x,y) = 0 otherwise
- If P(x,y) >= T for a threshold value T, (x,y) is determined to be a peak.

Valley detection algorithm is a closing morphology. The dilation is performed first followed by erosion. The overall valley detection process is simplified as the following;

- Find point (i,j) in half sphere r, find corresponding value of g(i,j)
- Perform grayscale dilation and obtained D(x,y)
  D(x,y):=max{I(x-1,y-1) + g(i,j)}; (-5<= i <=5)
- Grayscale erosion is performed onto D(x,y) and stored into R(x,y)
  R(x,y):=min{D(x-1,y-1) - g(i,j)};
- Perform V(x,y) = R(x,y) – I(x,y) for each pixel (x,y)
  V(x,y) = 1 if (x,y) is a valley pixel
  V(x,y) = 0 otherwise
- If V(x,y) >= T for a threshold value T, (x,y) is determined to be a valley.

B. *Image impose*

The resulting image from valley detection is imposed to the resulting image obtained from peaks detection. The algorithm to obtain the blood vessel as the following;

If (V[i][j] = valley OR P [i][j] = peak)
*result[i][j] = 255 / *indicate the blood vessel*/*
else
*result[i][j]=0 /*indicate the background*/*

i and j indicate the width and the height of the image meanwhile P[i][j] is an array that hold the peak value. V[i][j] hold the valley value and result[i][j] hold the value after the overall operations.

III. EXPERIMENTAL RESULTS

In this paper three (3) databases are utilized to experiment the proposed methods namely STARE, DRIVE and personal database. The original image is extracted into different channels namely red, green and blue. The red channel is used to extract the retina from the background meanwhile for further process only green channel will be employed. Next, image inversion based on the green channel image is obtained. Fig. 3 and Fig. 4 show the green channel image and the inversion image.

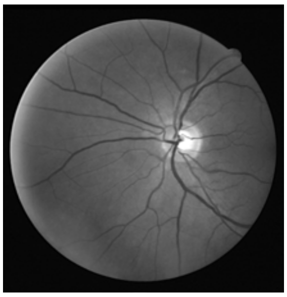

Fig 3 The green channel image

Fig. 4 The inversion image based on the green channel

Median filtering using 3 by 3 windows is utilized to smooth the image without blurring the blood vessel for both images (green channel and inversion image). A large windows size tends to blur the image and eliminate the small vessel information.

In the next process, both images (green channel and inversion image) undergo the peak and valley detection (as explained in Section II). The green channel image will utilize the valley detection method since blood vessel appears in low intensity. On the other hand, in the inversion image, the peaks detection will be employ. The blood vessel appears in high intensity for the inversion image. Both methods tend to detect the blood vessel. However, the inversion image provides more blood vessel information. Fig. 5 and Fig. 6 indicate the resulting image for peak and valley detection.

Fig. 5 Valley detection onto the green channel

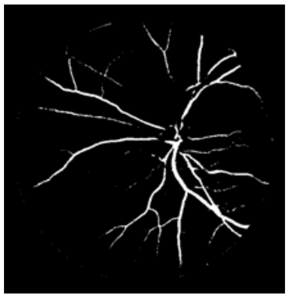

Fig. 6 Peak detection onto the inversion image

In order to acquire the overall blood vessel information, both images are combined as explained in Section II.

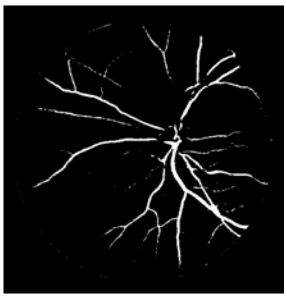

Fig. 7 Combining peaks and valley detection

Fig. 8 indicates the original green images in the left side meanwhile the image after combining the peaks and valley detection is shown in right side.

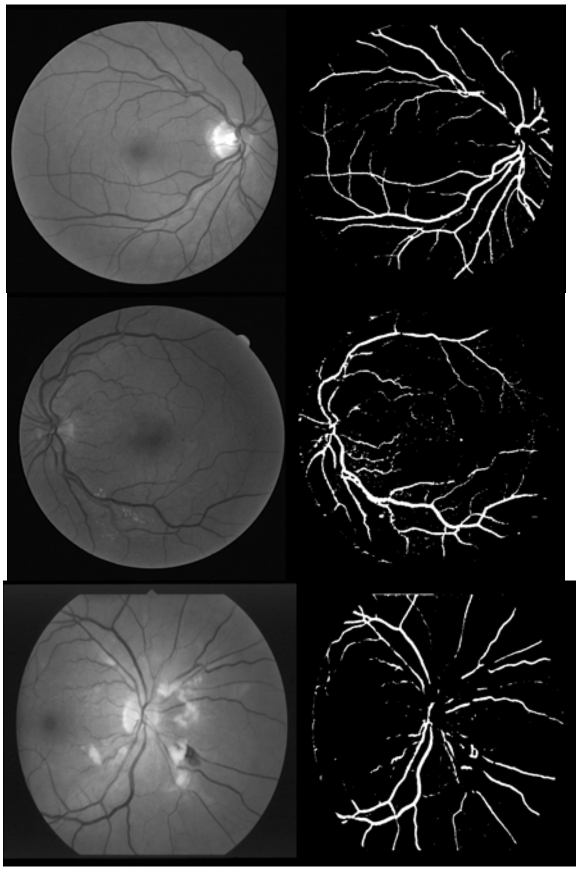

Fig. 8 Original green image (left) and resulting image (right)

Although the resulting image detects the blood vessel but it still fail to detect small vessels. Besides, unrelated information is detected. In the next phase, the image needs to be cleaned by removing the unwanted information and tracking down the missing vessels. However, the mention process above is beyond the scope in this paper.

IV. CONCLUSION

This paper proposed utilizing morphological operation in detecting the blood vessel. Peak and valley detection algorithm based on the green channel image and the inversion image are employed. Then, both resulting images are combined. The result shows that the vessel can be detected using the proposed methods. However, further methods need to be employed to clean the unwanted information and to track down the missing vessels from the previous resulting image.

ACKNOWLEDGMENT

The authors wish to thank the local hospital for assisting the image acquisition process for this research.

Abstract: In this paper we proposed a decision tree approach for fault diagnosis of nonlinear systems using tree model CART (classification and regression trees) and MNN (multilayer neural network). In the proposed method, the fault is detected when the errors between the actual system output and the NN nominal system output cross a predetermined threshold. Once a fault in the nonlinear system is detected, CART is used for classifying the fault.

Keywords: CART , fault diagnosis, MNN, nonlinear system

1 INTRODUCTION

There have been many methods for fault diagnosis of the system. These methods fall into two major groups: 1) model free methods, 2) model based methods. The model based fault diagnosis methods are dependent on finding a system mathematical model that defines the relationship between the system inputs and outputs. In practice, however, the mathematical description of the relationship is not easy to obtain due to nonlinearities. To overcome this problem, it is necessary to find the modeling tool of presenting any nonlinear relationship approximately. In recent years, NN(neural network) models have been studied considerably for the fault diagnosis problem [1-3]. Main advantages of the NN model for fault diagnosis applications can be represented by approximating the nonlinear functions and by adaptive learning and parallel processing. Hence this model can be used as a powerful tool for handling nonlinear problems.

This paper presented a decision tree approach for fault diagnosis of nonlinear systems using tree model [4] and MNN [5]. In the proposed method, the fault is detected when the errors between the actual system and the NN nominal system output cross a predetermined threshold. Meanwhile CART is used for classifying the fault. The algorithm contains two main parts: a fault detection part by threshold test and a fault classification part by CART.

2 PROPOSED FAULT DIAGNOSIS METHOD USING NN AND CART

2.1 Fault detection using neural network

Consider a discrete-time nonlinear system,

$$\begin{aligned} y(k+1) = g[\,y(k),\, y(k-1),\, \cdots, y(k-n+1), \\ u(k),\, u(k-1),\, \cdots, u(k-m+1)] + \varepsilon(k) \end{aligned} \quad (1)$$

where $u(k)$ and $y(k)$ are the input and the output at time k , respectively, and $\varepsilon(k)$ is the white noise.

In the proposed method, NN nominal system is utilized to detect the fault in nonlinear system. Therefore, MNN`s with BP learning algorithm is adopted in this study [5].

Fault is detected by the following threshold test

$$J_n(k) = \sum_{i=k-L+1}^{k} e_n^2(i) \; > \; \delta_f \quad (2)$$

where $e_n(k) = y(k) - y_n(k)$ is the error between the nominal system output and actual system output. $y_n(k)$ is the NN nominal system output, δ_f is the predetermined threshold for fault detection, L is moving window length.

If the estimated parameters converge to system parameters, then the error between the system output and estimate NN output has a similar property of the system noise. Thus, the error e_n has a normal distribution. Also, the sum of the normalized square errors in the moving window has a χ_L^2 -distribution with L degrees of freedom as follows:

$$\bar{J}_n(k) = \sum_{i=k-L+1}^{k} \frac{e_n^2(i)}{\sigma^2} \; \sim \; \chi_L^2 \quad (3)$$

If the false-alarm probability limit α is

$$\Pr\Big(\sum_{i=k-L+1}^{k} \frac{e_n^2(i)}{\sigma^2} > \delta^\circ \Big) = \alpha \quad (4)$$

and the threshold is obtained as: $\delta_f = \sigma^2 \delta^\circ$

2.2 Fault classification using decision tree algorithm

The decision tree consists of two parts, tree building and tree pruning. In the stage of tree building the initial state of a decision tree, called the root node, is the first internal node, to which all the patterns of the training set are assigned. If the training example consists of all the same class, then there is only a need for the root node. Conversely, if the training examples at the root node consist of two or more classes, a test node is made that will split the training set into two sub-spaces, or secondary nodes. These can either become terminal nodes, in which a classification is reached, or another test node. The process is recursively repeated until each branch results in a terminal node and a completely discriminating tree is obtained.

The tree obtained by the tree building step may have a large number of branches which substantially increase the tree's complexity. This could lead to encountering the familiar problem of over-fitting and overspecializing toward the training data. If that happens, the tree may not generalize well for new data sets and thus it is necessary to prune the tree to build smaller tree models. CART uses a tree pruning technique based on the principle of minimal cost complexity pruning which is also known as weakest sub-tree shrinking.

3 SIMULATION RESULTS

The nonlinear system is given as

$$y(k) = \cos(3.14\,p_1)\,y(k-1) - 0.7\,y(k-2) + u(k-1) + p_2\,u(k-2) + \varepsilon(k) \tag{5}$$

where, input $u(k) = 0.5\cos(k)$, $\varepsilon(k)$ is white noise with variance $\sigma^2 = 2.56*10^{-4}$, p_1 and p_2 are physical parameters and $p_1 = 0.56$, $p_2 = 0.37$. Here, we choose $\alpha = 0.01$ (1%) and L=30, fault threshold $\delta_f = 0.013$. NNs for fault detection is consists of 4 inputs, one hidden layer with 10 nodes, and one output node. The weights of the NN are adjusted at every time step using a learning rate $\eta = 0.15$, and momentum term $\alpha = 0.1$.

To verify the proposed diagnosis algorithm, one type of fault is the introduced to the system at the 150-th sample number. The following fault is simulated

Fault #1: p_1 is decreased ($p_1 = 0.35$)

The prepared 20 data sets for each system condition (normal, fault #1) were used for training of CART. Fig. 1 shows a classification tree built by CART taking the 15 input data.

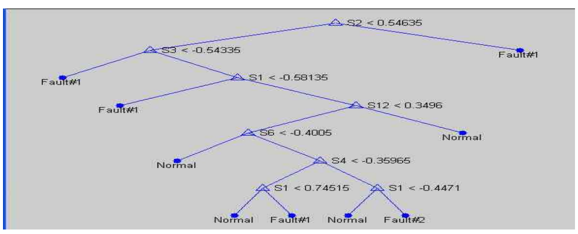

Fig. 1. Trained CART classification tree.

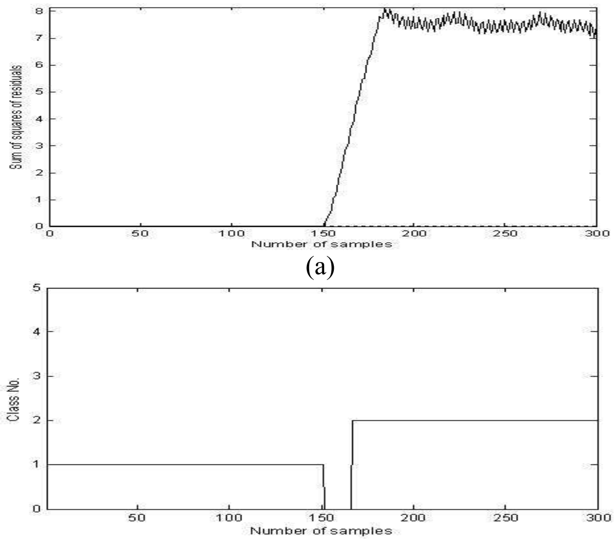
Fig. 2(a) shows the variations of the sum of squares of errors in the moving window, and 2(b) plots fault isolation results by CART. The simulation results show that CART successfully isolates the fault of the nonlinear system.



(a)

(b)

Fig. 2. Results of detection and isolation for fault #1.
(a) Change of J_n and fault detection (dashed line: δ_f)
(b) Classification results by CART

4 CONCLUSION

In this work, we develop a fault diagnosis method using CART and MNN to detect and isolate faults in nonlinear systems. The decision tree is proficient at both maintaining the role of dimensionality reduction and at organizing optimally sized classification trees, and therefore it could be a promising approach to diagnose a fault which is occurred in the systems. Simulations are carried out to evaluate the performance of the proposed NN-based diagnosis method.

Abstract: We usually read in newspapers about fire accidents and rising death toll rates because of fire related accidents. At times even firemen lose their lives while on rescue operations. We have proposed a model Fire Fighting Robot which has been designed for relief operations with main focus on rescue purposes. Use of robots is growing both on Earth and in space, in large part due to increased capacity for machine intelligence. Robotics defined as a mechanical design that is capable of performing human tasks or behaving in a human-like manner. The Robot is an electrically powered and remotely controlled unmanned vehicle. It is a battery-operated robot on wheels and its primary role is to detect the source of heat and put off flames.

Keywords: Autonomous, Fire Extinguishing, Obstacle detection etc.

1 INTRODUCTION

The Proposed firefighting robot is designed to detect the source of fire with its strong sensor technology integrated with it. We have read some past articles about firefighting robots but we have seen that cost has always been a neglected issue. We have proposed a micro-controller based firefighting robot (ATMEGA-32) [1] which is not only *cost-effective* but also *highly efficient* and *reliable* in its primary purposes. Robotics does not always need to be expensive and it should be designed for mass people. We have carefully chosen our materials surrounded beside us and we want to assemble different technologies for manipulating its main purposes. We have arranged the topics consequently in this paper to maintain the coherence among the discussed topics. Main features of this Robots are-

1. Heat and Smoke Sensor
2. Obstacle Detector
3. Traction System
4. Fire Extinguishing
5. Low battery sensor
6. Wireless Controlling System

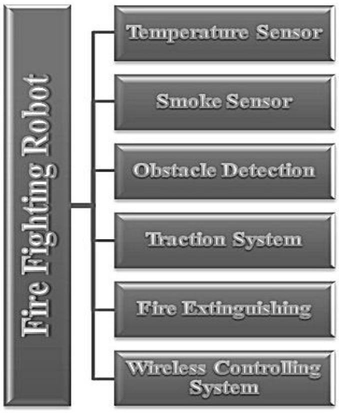

Fig1: Fire Fighting Robot Functions

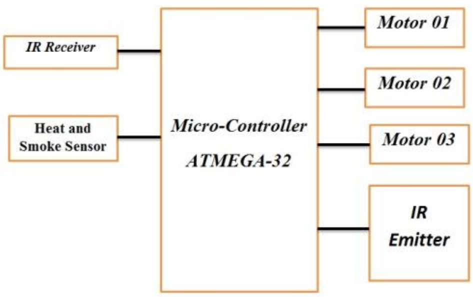

Fig2: Micro-Controller ATMEGA32 pin connection for some parts of the Robot

2 DESIGN

2.1 Heat and Smoke Sensor:

We have used CM-WTK55 as our heat and smoke sensor. The *photoelectric* type smoke part of detector is based on the photoelectric sensing principle [2]. When fire break out and smoke enters the light tight box, the particles of smoke scatter the infrared light, and this scattered light goes into the receiving element, there by emitting an electric current, and while the electric current is up to the fixed extent, the fire alarm will be activated. The fixed temperature heat detector part has stabilized performance, long-term durability and least -malfunction are ensured by employing a bimetal mechanism, which meets UL verification .Its temperature setting is 55°c. [3]

2.2 Obstacle Detection

As we have proposed that our robot is an *autonomous* one it has an efficient system to avoid the obstacles. To detect any kind of obstacles we have used *IR detection system*. We have used IR led for infrared emission .

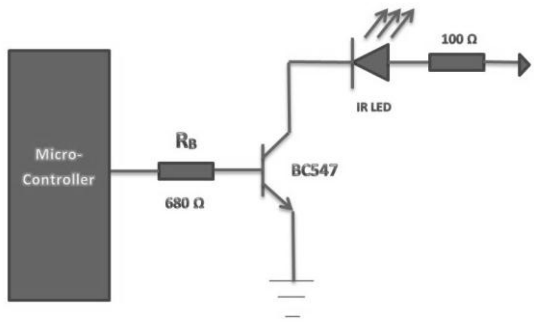

Fig 3: Block diagram of IR emitter

And we have also designed a receiver to receive the reflected IR so that our robot can move avoiding all the obstacles. We placed IR emitter and receiver on the robot in a manner so that it can sense objects and walls surrounding it.

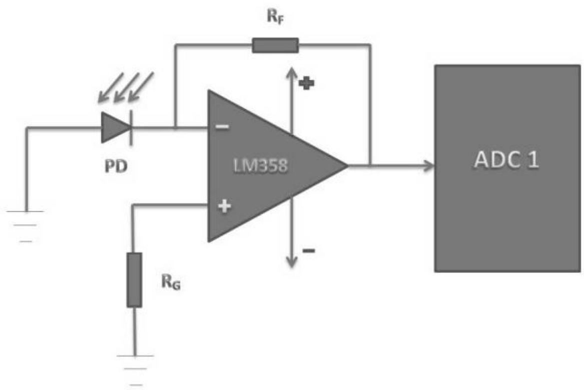

Fig 4: Block diagram of IR receiver

2.3 Traction System:

We have used two *permanent magnet dc motors*. Most of the work, power delivered to the shaft in the form of torque, is done by the permanent magnets. Because power is consumed for only a brief period of time upon each alignment of the permanent magnet and electromagnet, very little power is necessary to run the motor-generator, making it *highly efficient*. The benefits of using permanent magnet dc motors are-wide availability, cost effectiveness, Adequate Power Supply [4]. The movement of our proposed Robot models depends on the rotation of two wheels. If both of the wheels rotate clockwise our robot will move forward. The robot will move backward when both of the wheels rotate anti-clockwise. When the Right side wheel is off, the left side wheel is rotating clockwise, So the robot will turn right at that time and similarly the robot will turn left when the left wheel remains still.

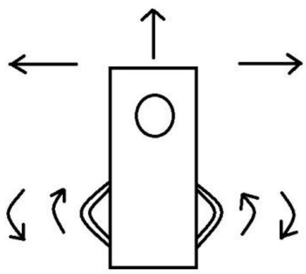

Fig 5: Traction system

2.3.1 Sample programming for traction system

```
Sub Forward

Cls

Lcd "FORWARD"

Pwm1b = 200

Portd.3 = 0

Pwm1a = 200

Portd.6 = 0

End Sub
```

2.4 Wireless Controlling System

We have followed the Manchester coding system for Wireless Controlling. We have modified according to our demand.

2.4.1 Manchester Coding

Manchester coding works on transitions from high to low (bit 0), or low to high (bit 1), the actual width of the pulses doesn't matter particularly (within reason).This is the way the bits are actually sent, a bit 1 is a transition from 0 to 1, and a bit 0 is a transition from 1 to 0 [5].For RF transmission there is a huge possibility in case of receiving a data. So we hane used a *packet system*, where a number of different pieces of information are transmitted after each other in the form of a 'packet', this consists of a number of different sections like header section , address byte, data and checksum.

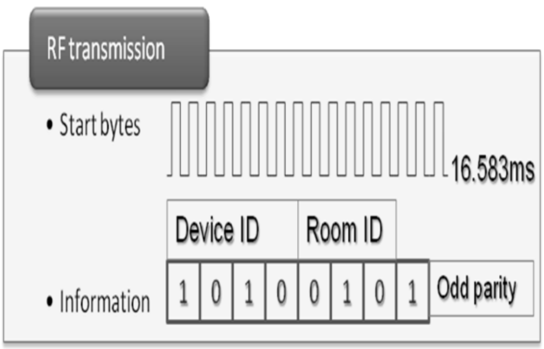

Fig 6: Manchester coding system

The *header* section consits of a row of 20 bit one's followed by a single bit zero.

The long sequence of 1's gives the receiver time to settle and the decoding software time to synchronise.

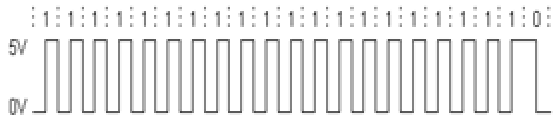

Fig 7: Header

The *address section* consists of the 8 bits of data in the byte, followed by a single bit one, and a single bit zero.

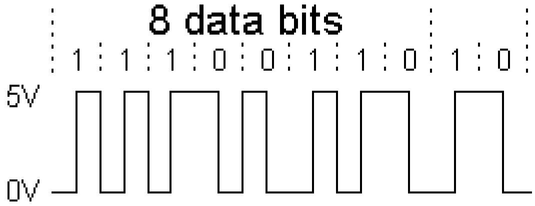

Fig 8: Address byte

Data and checksum are same as address 8 bits.

2.5 Materials

For the robot designing, we used *Aluminium* because it is very strong, light, resistant to corrosion, and affordable. To slow down the heat flow between the outer and inner shells, the gap is filled with rock wool and ceramic paper as insulation material. Most importantly, it is very easy to cut, shape, drill, and bend. Aluminum has a much higher strength to weight ratio. This means that for a mass of aluminum and an equal mass of steel, aluminum would be much stronger. Another important thing about aluminum is that it is resistant to rust. In actuality, aluminum does rust, but it quickly forms an oxidized layer which acts as a protective coating against any further rust. Aluminum has a very high thermal conductivity. We have chosen worm gearing as our gearing because it available, cost effective.

2.6 Low battery sensor

A low battery sensor measures current, voltage from battery, if battery contains lesser voltage or current than standard this circuit will work. A warning alarm will be triggered when battery voltage is lower than the voltage or current level set by the user. As we used 9.6V battery we set the voltage level at 7V, which means this circuit will trigger alarm when the battery voltage is lesser than 7V [6].

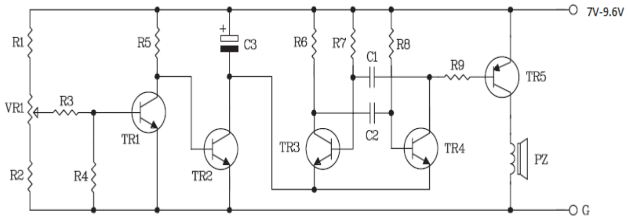

Fig 9: Circuit diagram of low battery sensor

2.7 Power Supply

The power of the robot is supplied by two 9.6 V rechargeable NiCd batteries. The Transmitter battery pack contains NiCd (Nickel-Cadmium chemical composition) rechargeable that provide significantly more energy than comparable AA NiCd batteries. The Battery Pack's cells will provide a constant reliable voltage until they are exhausted. Contrary to popular belief, NiCd batteries do not suffer from any sort of permanent "memory effect". Rechargeable NiCd batteries can be used over and over again for hundreds of battery cycles if properly maintained [7]. However, all batteries will eventually wear out over time.

2.8 Fire Extinguishing

A fire extinguisher or extinguisher is an active fire protection device used to extinguish or control small fires, often in emergency situations**.** For *extinguishing fire* we used *CO_2 and water* [8]. We have placed rotating nozzles in all corner parts of the robot so that it can cover every possible part of a room. Both the extinguishing system will be activated when temperature reaches the set value and smoke is sensed by the sensor. To spray water we used Zodi Outback Gear Zodi 6 Volt which can Pump [9] about 1/2 gallon per minute and weighs only 1lbs.

3 CONCLUSION

Our proposed low cost robot model can move avoiding obstacles and detect fire source without any kind of false alarm. Depending upon the fire intensity it will use the extinguishers attached to it. Our robot can be autonomous and we can also control it by RF transmission. We are currently working on image processing and video feedback system so that we can learn about the inner situation of the room. We are also working on machine learning so that our robot can remember the mistakes and take certain intelligent decision by him. We are trying to make our robot even more cost effective. Our main concern is to make the robot effective in very high temperature. The main deficiency of our proposed robot model is that it is not able decide what kind of extinguisher it would use. We are working on that problem.

Abstract: In this paper, a novel method is proposed to analyze the gait using inertial sensor and vision technique. An indirect Kalman filter is used to estimate step length and foot angles. The vision technique provides us vision information which is used to update the Kalman filter. A measurement unit including a camera and inertial sensors is mounted on a shoe. The vision information including position and attitude of a shoe is estimated based on a simple planar landmark system which consists of thousands of markers and be easily expandable. Experiments verify our proposed system is quite accurate, especially in step length measurement. This proposed system is suitable for long distance applications.

Keywords: gait analysis, image processing, inertial sensors, position estimation.

1 INTRODUCTION

Gait analysis [1] involves the measurement of temporal/spatial characteristics (step size and walking speed), kinematics and kinetics. Gait analysis is used for medical purpose, sport analysis and also for entertainment.

In this paper, a new gait analysis system is proposed. A measurement system consisting of a camera and inertial sensors is installed on a shoe. Fiducial markers [2] are printed on paper and placed on the floor. Fiducial markers are used mainly in virtual reality systems. There are many types of markers. Since there are no concerns that complicated backgrounds are mistakenly recognized as markers, we used simple markers in this paper.

When a foot is on floor, the movement is estimated using a camera. When a foot is moving, its movement is estimated using inertial sensors. In an inertial-based foot estimation system, Kalman filters are usually used to estimate foot measurement. For better accuracy, a smoother [3] is used to combine vision data and inertial sensor data.

The paper is organized as follows. In Section 2, formulation problem of the proposed system is given. In Section 3, experimental results are given. Conclusion is given in Section 4.

2 FORMULATION PROBLEM

2.1 Gait analysis system

The gait analysis system consists of a sensor unit on a shoe and fiducial markers on the floor (**Fig. 1. (a)**). A sensor unit consists of a camera (point grey Firefly MV FFMV-03MTM) and inertial sensors (XSens MTi inertial measurement unit).

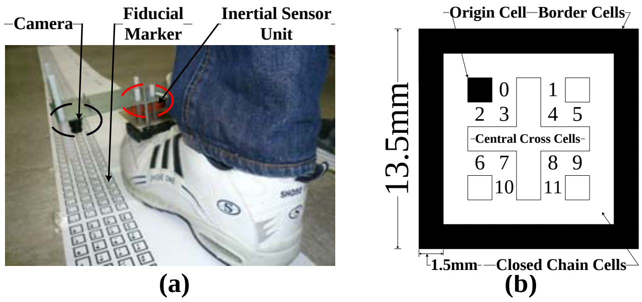

Fig. 1. Gait analysis system and marker's structure

A fiducial marker is similar to ARTag markers [2] and its structure is shown in **Fig. 1(b).** The marker is a nine by nine grid of quadrilateral cells of 1.5 millimeter edge including origin cell, border cells, central-cross cells and closed-chain cells. The marker has twelve bits digital coding system inside. The code bits are distributed along the quadrilateral central-cross in the order from left to right, and from top to bottom. A planar landmark system is generated by N fiducial markers which are composed of a four by M grid of markers as in **Fig. 2.** make it be easily expandable. The marker ID is encode from 0 to $(N-1)$.

2.2 Coordinate frame assignment

There are four coordinate frames in this paper. The world frame is located at the first marker of the planar landmark system. Positions of a foot are expressed in this frame. The navigation frame is used in an inertial navigation algorithm. It has the origin as same as that of the world frame. The camera frame is placed at the pinhole of the camera, where the Z axis perpendicular to the image plane. The last frame is body frame which has three axes coincide with those of inertial sensors. In this paper, it is assumed that three axes of the camera frame and the body frame are the same.

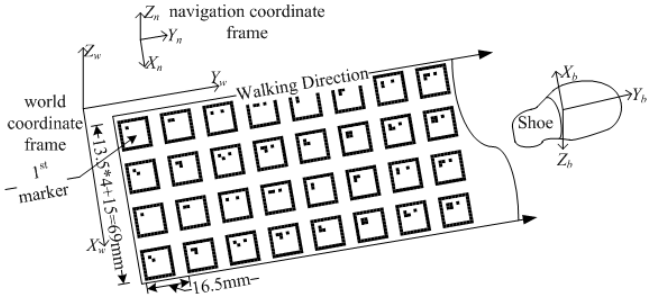

Fig. 2. Planar landmark system and frame assignment

2.3 Position and attitude estimation using markers

When a foot is not moving on the floor, markers in camera image are recognized through an image processing process in which the marker's ID and its outer four corners coordinates are extracted.

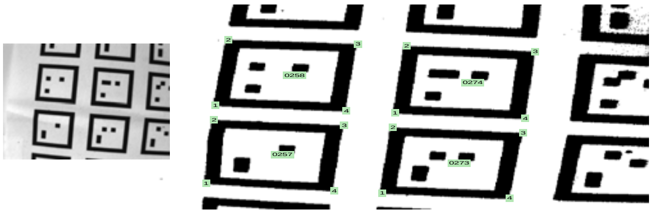

Fig. 3. Origin image and four extracted corners

Position $\left(\hat{r}_{vision}\right)$ and attitude $\left(\hat{C}_{vision}\right)$ of a camera with respect to the world frame are determined using the four corners coordinates and based on the algorithm in [4]. Let r_w be a point expressed in the world frame and r_b be the same point in the body frame. Then the relationship between r_b and r_w is given by

$$r_w = \hat{C}_{vision} r_b + \hat{r}_{vision} \qquad (1)$$

2.4 Position and attitude estimation using inertial data

When a foot is moving, position and attitude are estimated using an inertial navigation algorithm. Firstly, zero velocity intervals are detected [5]. An indirect Kalman filter [6] with state vector $x = \left[q_e \quad v_e \quad r_e\right]'$ is used in forward direction and backward direction. Then a smoother is applied to obtain the best accurate estimation of position and attitude.

3 EXPERIMENTAL RESULT

The camera is firstly calibrated to obtain its intrinsic. In our experiments, the sampling rate of camera and inertial IMU sensors are 30fps and 100Hz, respectively. A person who wears the shoe (**Fig. 1(a)**) is required to free walk along a planar marker system path (**Fig. 2**). Through the experiment shown in **Fig. 4,** it is proved that the position are accurately estimated.

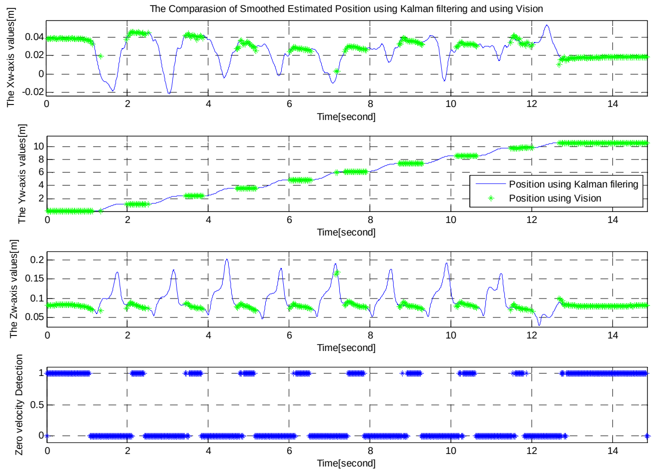

Fig. 4. Position Estimation

4 CONCLUSION

A novel approach was decribed for position and attitude estimation using integration of vision and inertial sensor. In vision, the planar landmark path is easily expandale when longer walking range is need in such application as a clinical gait assessment of patients, parameter estimation of some pedestrian navigation algorithms.
